From the blood, infection is spread to distal lymphoid tissue and to epithelial cells, endothelial cells, and macrophages in multiple organs.^{197,460} Transmigration across an endothelial barrier is impaired for MeV-infected lymphocytes,¹⁶⁶ so entry of MeV into tissues may occur primarily from endothelial cells infected by circulating leukocytes or by movement of other types of infected cells, such as monocytes, across blood vessel walls.⁴¹³ Once within tissue, spread is cell type and virus strain dependent and occurs by cell–cell fusion or by release of infectious virus. Tyrosine residues in the cytoplasmic tails of F (aa 549) and H (aa 12) are important for basolateral glycoprotein sorting and determine the fusogenic spread of MeV in epithelial cells.^{462,463} However, only the H sorting signal determines wild-type MeV release versus cell–cell fusion in lymphocytes.^{609,610}

Lymphoid organs and tissues (e.g., thymus, spleen, lymph nodes, appendix, and tonsils) are prominent sites of virus replication⁶¹⁷ where infection results in the appearance of lymphoid or reticuloendothelial giant cells first described by Warthin⁷⁵⁹ and Finkeldey.²⁰⁸ These cells can be 100 μm or more in diameter and contain up to 100 nuclei aggregated near the center. Inclusion bodies are not generally present. Warthin-Finkeldey cells tend to be located in or near germinal centers, in the thymus, and in submucosal lymphoid tissue.^{279,509} In the thymus, infection of epithelial cells and thymocyte apoptosis lead to a prolonged decrease in the size of the thymic cortex, while other lymphoid tissues recover promptly.⁷⁷²

MeV also spreads to the skin, conjunctivae, kidney, lung, gastrointestinal tract, respiratory mucosa, genital mucosa, and liver (Fig. 36.11). In these nonlymphoid sites the virus replicates primarily in endothelial cells, epithelial cells, and macrophages.^{197,198,460,699} Endothelial cell infection may be accompanied by vascular dilatation, increased vascular permeability, mononuclear cell infiltration, and infection of surrounding tissue.¹⁵⁰ The histopathology of the measles rash suggests that the initial event is infection of dermal endothelial cells³⁵⁵ followed by spread of infection into the overlying epidermis with infection of keratinocytes in the stratum granulosum leading to focal keratosis and edema.⁶⁹⁹ Epithelial giant cells form and mononuclear cells accumulate around vessels.¹⁵⁰ Koplik spots found on the oral mucosa are pathologically similar and involve the submucous glands.¹⁵⁰

On rare occasions there is spread to the nervous system. *In vitro* studies have demonstrated infection of brain microvascular endothelial cells by adherent MeV-infected T lymphocytes,¹⁶⁶ and infection of endothelial cells has been demonstrated in the brains of children dying of measles.^{197,358} Polarized endothelial cells can release virus from both the apical and basolateral cell surfaces, allowing access to the brain parenchyma, as well as the blood.¹⁶⁶ If neurons become infected, virus can spread through the central nervous system (CNS) from neuron to neuron without the release of infectious particles.¹⁷⁷ It has been suggested that the F protein interacts at the synapse with the substance P receptor neurokinin-1 to mediate transsynaptic spread.⁴¹⁹

Immune Responses

The immune responses to MeV are important for clearance of virus and recovery from infection and are directly responsible for several of the clinical manifestations of measles. Although infectious virus cannot be isolated after the rash is cleared, viral RNA can be detected for many weeks, indicating that complete viral clearance is a prolonged process.^{529,542,734} The roles of various components of the immune response in recovery from infection have been deduced from *experiments of nature* in which the outcome of MeV infection in patients with deficiencies of immunologic function has been documented and from the studies of monkeys depleted of specific components of the immune system.^{244,539,540,542} In general, deficits in antibody production permit recovery, while deficits in cellular immune responses may lead to slowed clearance and progressive disease (see Measles in the Immunocompromised Host later). In immunologically normal individuals, the onset of clinically apparent disease coincides with the appearance of the MeV-specific adaptive immune response. There is also marked activation of the immune system that is coincident with the appearance of immune suppression (Fig. 36.11). Immune suppression and immune activation continue for many weeks after apparent recovery.

EARLY INNATE RESPONSES

Innate responses may contribute to control of virus replication during the incubation period, but determining the role and importance of specific components of the innate response in measles has been complicated. *In vitro* studies have shown that innate responses triggered by interaction of MeV RNA or proteins with pathogen recognition receptors at the cell surface or in the cytoplasm to activate signaling pathways involving transcription factors nuclear factor- κ B (NF κ B) and IRF-3 differ with the strain of virus, are cell type specific, and are highly regulated by the viral P, C, and V proteins.^{63,172,284,345,625,646,718} Epithelial cells show activation of NF κ B and activator protein-1 (AP-1)³²⁰ and production of the chemokine CXCL8 (interleukin-8 [IL-8])⁶²⁹ after MeV infection. However, monocytes respond differently than epithelial cells, and interaction of H with TLR2 at the monocyte cell surface stimulates induction of IL-6 and increases surface expression of CD150,⁶³ while interaction with CD46 inhibits IL-12 production.³⁴⁴ The NF κ B pathway and tumor necrosis factor- α (TNF- α) production are suppressed in MeV-infected monocytes, potentially as a result of MeV P protein-induced up-regulation of the ubiquitin-modifying enzyme TNFAIP3 (A20), a negative regulator of NF κ B.^{393,629,756}

Some inflammatory cytokines and chemokines are induced *in vivo* during measles. Levels of IL-1 β and IL-8 are increased in plasma of children during measles,^{629,807} and infected macaques

show increases in IL-6 and IL-8.⁶²⁶ IL-1 β mRNA and protein are increased in MeV-infected monocyte-derived cells and in PBMCs cultured from patients after rash onset.^{393,756} Transcriptional analysis of PBMCs from children with measles has shown increases in mRNAs for cytokines IL-1 β and TNF- α and chemokines CCL4 (MIP-1 β), CXCL2 (MIP-2 α), and IL-8.⁸⁰⁷ The mRNA for CIAS-1 (NALP3), a component of the inflammasome responsible for processing proIL-1 β to its active form, is also increased.⁸⁰⁷

Type I IFN is an important component of the innate response to many virus infections, and MeV replication is sensitive to the inhibitory effects of IFN- α/β .^{391,640,714} MeV replication is required for induction of IFN- β transcription in most responsive cells.²⁸⁸ Two induction mechanisms have been identified. In epithelial cells, MeV leader RNA can interact with and activate RIG-I and, to a lesser extent, MDA5,^{318,555} and N can interact with and activate IRF-3 in concert with an unidentified cellular co-factor.^{128,718} Induction of IFN by MeV may also occur at the cell surface through interaction of the virus with CD46 or TLR2.^{63,345} *In vitro*, MeV infection of epithelial cells and DCs leads to rapid production of IFN- β and many IFN- α s followed by induction of IFN-responsive genes.^{463,625,633,714,808} On the other hand, MeV infection of mitogen-stimulated PBMCs does not usually stimulate IFN production.⁴⁹⁸ In fact, MeV suppresses type I IFN production and signaling in CD4+ T cells⁶²⁵ and has a variable effect on plasmacytoid DC IFN production.^{169,633}

Many of the reported effects of MeV on immune cell function *in vitro* are secondary to the effects of IFN. For instance, MeV induction of IFN inhibits development of DCs but stimulates maturation of immature DCs and terminal differentiation of cortical thymic epithelial cells.^{270,741} IFN also plays a role in suppressing proliferation of T cells in cultures of MeV-infected PBMCs.⁶¹⁹ However, interpretation of investigations related to IFN induction and its role in measles pathogenesis has been confounded by the frequent presence of 5' copy-back DI RNAs in the stocks of the virus strains studied.^{352,662} Vaccine strains are more likely to induce IFN- α/β than wild-type strains,⁴⁹⁸ but this may be related to the efficiency with which they generate DI RNAs,^{352,662,701} which are potent inducers of IFN through activation of MDA5.^{688,800}

It is not clear whether IFN- α/β is induced during MeV infection *in vivo*. Transcriptional analysis of PBMCs during measles shows no evidence of up-regulation of IFN-induced genes.⁸⁰⁷ No IFN- α/β has been detected during natural infection in humans or experimental infection of macaques.^{259,262,476,664,801} Biologically active IFN has been detected occasionally, but IFN- γ produced by T cells is produced in response to infection, and the protein responsible for IFN activity (type I or II) was not identified.^{543,626} A recombinant wild-type MeV that cannot interfere with STAT1 translocation is attenuated in macaques, suggesting some role for this signaling pathway in the response to infection.¹⁵⁶

Natural killer (NK) cells constitute another potentially important early defense mechanism, but studies of NK activity indicate that NK cell function is actually lower than normal during measles.²⁶² These studies were performed using samples collected at, or after, the rash, so they do not exclude NK cell activation at earlier stages of infection.

MeV and MeV-infected cells activate the factor B-dependent alternative complement pathway, rendering the cells susceptible to complement-mediated lysis.⁶⁷⁵ This is a property of F₁

and results in deposition of C3b on the virion and infected cell surface independent of virus use of the complement regulatory protein CD46 as a receptor.¹⁵⁴ In infected cells, the complement regulators CD46 and CD55 are segregated into separate membrane microdomains from F.²³³

ANTIBODY

Antibodies are first detectable when the rash appears^{55,75,249} (Fig. 36.11). The isotype of MeV-specific antibody is initially IgM followed by a switch first to immunoglobulin G2 (IgG2) and IgG3 and then, in the memory phase, to IgG1 and IgG4.^{75,322} IgG is initially of low avidity and this improves steadily over several months.^{488,726} IgA, IgM, and IgG antibodies to MeV are found in secretions and sampling of saliva has provided a noninvasive method for determining immune status.^{81,317}

Antibodies are eventually produced to most viral proteins (Fig. 36.12). The most abundant and most rapidly produced antibody is to N.²⁴⁹ Because of the abundance of anti-N antibody, absence of this antibody is an indicator of seronegativity. The M protein elicits only small amounts of antibody, except in atypical measles.^{249,415} Antibodies to H are the primary antibodies that neutralize virus infectivity.^{144,145,237} Neutralization is generally measured by plaque reduction of the Edmonston strain of MeV on CD46-expressing Vero cells,¹²⁵ but this assay may not reflect neutralization of the infection of wild-type MeV strains on SLAM-expressing cells.⁵⁵⁹ Neutralizing epitopes have been mapped by competitive binding of monoclonal antibodies and by analysis of different strains and escape mutants (Fig. 36.8).^{307,312,396,658} Human convalescent sera show reactivity to linear epitopes, as well as to epitopes dependent on conformation and glycosylation.^{305,451,482} A highly conserved linear neutralizing epitope is in the H noose (aa 379 to 410).⁵⁷⁰

Major conformational epitopes have been localized to regions between amino acids 368 and 396 and in the SLAM-binding region.^{192,396} Essentially all of these epitopes are on exposed surfaces on the sides of H (Fig. 36.8).^{276,622} Antibodies to F induced by regions encompassing amino acid 73 and amino acids 388 to 402 contribute to virus neutralization, probably by preventing fusion of the virus membrane with the cell membrane at the time of virus entry.^{25,144,201,420,420,557} Human sera also recognize linear epitopes in six to seven regions spread over much of the F protein frequently close to T-cell epitopes.^{481,778}

Antibody can protect from MeV infection, may contribute to recovery from infection, and may play a role in establishing persistent infection.^{9,186,577} Antibody-dependent cellular cytotoxicity correlates temporally with cessation of cell-associated viremia,²¹² and failure to mount an adequate antibody response carries a poor prognosis.⁷⁷⁰ However, in monkey studies transient depletion of B cells does not affect clearance of infectious virus.⁵³⁹ Antibody binding to infected cells alters intracellular virus replication and may contribute to control of infection.^{218,240,639} The role of antibody in protection from infection is discussed under Vaccination and the role in establishing persistence is discussed under Persistent Infection.

CELLULAR IMMUNITY

The ability to recover from measles was postulated by Burnet to be an indication of the adequacy of T-lymphocyte-mediated immune responses,⁸⁶ and depletion of CD8+ T cells in infected monkeys impairs control of virus replication and slows clearance.⁵⁴⁰ MeV-specific, proliferating, and clonally expanded CD8+ T cells are present in blood at the time of the rash and in bronchoalveolar lavage fluid during pneumonitis.^{331,464,476,485,732,757} IFN- γ , soluble CD8, and β_2 -microglobulin, a component of

A: Percent of individuals positive for antibody to each protein. **B:** Relative amounts of antibody to each protein. Antibody was measured by immunoprecipitation. (Adapted from Graves MC, Griffin DE, Johnson RT, et al. Development of antibody to measles virus polypeptides during complicated and uncomplicated measles virus infections. *J Virol* 1984;49:409–412.)

the major histocompatibility complex (MHC) class I molecule, are increased in plasma.^{259,260,261,476} The H and M proteins can be processed and presented to CD8+ T cells in a transporter associated with antigen processing (TAP)-independent fashion.⁵⁰² Cultures of PBMCs with autologous MeV-infected or MeV peptide-pulsed cells after recovery show expanded CD8+ T cells that are cytotoxic and produce IFN- γ , demonstrating that effector CD8+ T-cell memory is established by infection.^{331,332,492,732} CD8+ T-cell responses in humans show a broad pattern of reactivity with epitopes identified in all viral proteins, except V.^{289,330,331,523,737–739}

CD4+ T cells are also activated in response to MeV infection. *In vitro*, binding of H to CD46 targets virion proteins to an endosomal compartment for efficient presentation by MHC class II molecules.²³² CD4+ T cells are proliferating during the rash.⁷⁵⁷ Soluble CD4 becomes elevated in plasma and remains so for several weeks after recovery.²⁵⁸ Classic CD4+ T-cell responses, such as MeV-specific proliferation and production of cytokines, and regulatory T cells are stimulated during measles.^{476,732,801} In immune individuals, most MeV proteins can induce lymphocyte proliferation.^{430,480,737}

Cytokines produced by CD4+ T cells determine their function. Type 1 CD4+ T (Th1) cells produce IFN- γ that activates macrophages and IL-2 that promotes T-cell proliferation. These are the primary mediators of classical delayed-type hypersensitivity. Type 2 CD4+ T (Th2) cells produce IL-4, IL-5, IL-10, and IL-13 that are important for B-cell growth and differentiation and for macrophage deactivation. Th17 cells are associated with autoimmunity and produce IL-17, while T-regulatory cells produce IL-10 and transforming growth factor- β (TGF- β). In measles, IFN- γ , neopterin (a product of IFN- γ -activated macrophages), and soluble IL-2 receptor rise during the prodrome, prior to the appearance of the rash.^{259,261} This is followed by elevation of IL-2, soluble CD4, and soluble CD8 at the time of the rash.^{260,261,476} As the rash fades, IL-4, IL-10, and IL-13 increase, and elevation of these cytokines persists in some individuals for weeks^{260,476,801} (Fig. 36.11). This pattern of cytokine production suggests early activation of CD8+ (IFN- γ) and type 1 CD4+ (IFN- γ and IL-2) T cells during the rash followed by activation of type 2 CD4+ T cells (IL-4, IL-13) and regulatory T cells (IL-10) during recovery.

IFN- γ may have an important direct antiviral effect. IFN- γ can suppress MeV replication in epithelial and

endothelial cells *in vitro* through induction of indoleamine 2,3-dioxygenase⁵¹⁰ and inhibits MeV replication in the brains of infected rodents.^{534,764}

LONGEVITY OF THE IMMUNE RESPONSE

Epidemiologic studies have documented that long-term protection from reinfection does not require re-exposure.⁵³⁰ Immunologic memory includes both continued production of antibody and circulation of MeV-specific memory T cells.^{69,302,493,732,784} The role of the slow or potentially incomplete process of MeV clearance from lymphoid tissue in establishing lifelong immunity to reinfection is unknown.^{542,589} Extensive replication of MeV in lymphoid tissue may maximize the interaction of viral antigen with antigen-retaining follicular dendritic cells in germinal centers,⁴⁴¹ leading to long-term antibody production.

IMMUNE SUPPRESSION

MeV can suppress immune responses *in vivo* during measles, *in vitro* when immune cells are cultured with virus or viral proteins, and in some animal models. It has not yet been possible to synthesize information from these various sources into a coherent understanding of increased susceptibility to other infections, the important clinical correlate of immune suppression.

During Measles. Measles was the first disease recognized to increase susceptibility to other infections, and most measles deaths are caused by other infections.⁵⁶ Increased susceptibility continues for weeks after the rash has cleared.²⁴⁷ Clemens von Pirquet first quantified the immunosuppressive effects of measles in his study of tuberculin delayed-type hypersensitivity skin test responses during a measles outbreak in a tuberculosis sanitarium,⁷⁵⁰ and this response is suppressed for weeks after the rash has cleared and recovery appears complete⁷¹² (Fig. 36.13). Reactivation of tuberculosis and remission of immunologically mediated diseases such as nephrotic syndrome, juvenile rheumatoid arthritis, and idiopathic thrombocytopenic purpura have been reported to follow measles^{121,401} but not always confirmed.³⁸⁴ Production of antibody and cellular immune responses to new antigens is impaired.¹³¹ *In vitro*, PBMCs from patients with measles have suppressed lymphoproliferative responses to mitogens and abnormal lymphokine production.^{294,756}

Immune suppression is probably a multifactorial process. Evidence of immunosuppression begins during a period of intense immune activation associated with the onset of the

FIGURE 36.13. Immune suppression during measles. **A:** Changes during measles in tuberculin-induced delayed-type hypersensitivity (DTH) skin test responses in children with measles who had previously received bacille Calmette-Guérin (BCG) immunization against tuberculosis. **B:** Changes in proliferation of peripheral blood mononuclear cells to the mitogen phytohemagglutinin. (Data from Tamashiro VG, Perez HH, Griffin DE. Prospective study of the magnitude and duration of changes in tuberculin reactivity during complicated and uncomplicated measles. *Pediatr Infect Dis J* 1987;6:451–454; and Hirsch RL, Griffin DE, Johnson RT, et al. Cellular immune responses during complicated and uncomplicated measles virus infections of man. *Clin Immunol Immunopathol* 1984;31:1–12.)

measles rash and generation of the immune response to MeV that eventually results in virus clearance and in lifelong immunity to reinfection (Fig. 36.11). *In vitro* studies suggest defects in the responses of both monocytes and lymphocytes. Monocytes and macrophages are infected during measles,¹⁹⁶ and monocyte function is abnormal with low levels of IL-12 and TNF- α production during both acute and convalescent phases of the disease.^{24,255,546,560} B cells and T cells, particularly CD4+ memory T cells, are also infected,^{143,441} with decreased numbers in circulation and reduced CD4:CD8 ratios during the acute phase of measles.^{23,141,256,613,757,773} Lymphocytopenia may be due to death of infected cells or to fever-induced changes in lymphocyte trafficking and is more marked in girls and in malnourished children.^{3,196,613} More severe disease has been associated with decreased CD4+ T cells.³⁵⁴ Induction of bystander lymphocyte apoptosis by MeV-infected cells may contribute to lymphocyte loss.^{27,217,379,517,752} Ligation of CD150 also favors CD95-mediated apoptosis.^{187,670} However, numbers of T cells in circulation rapidly return to normal during recovery, and output of naive CD4+ and CD8+ T cells from the thymus is sustained,^{28,541,729} while other immunologic abnormalities persist.^{29,253,613,756}

One of the reasons for low T-cell proliferation to mitogens *in vitro*, especially during convalescence, is inadequate production of IL-2, and supplementation supports spontaneous proliferation and improves mitogen responses of lymphocytes.²⁵⁶ There is persistent suppression of IL-12 production, lymphocyte expression of CD30, and elevation of IL-4, IL-10, and IL-13 after resolution of the rash (Fig. 36.11).^{96,258,546,742} Lack of IL-12 and induction of IL-10 may contribute to the type 2 cytokine responses that develop during recovery.^{258,476} *In vitro* production of IFN- γ is low to normal and IL-4 is high compared to controls,^{258,756} suggesting that type 2 CD4+ T cells are preferentially activated. The suppressive effects of IL-4 and IL-10 on type 1 CD4+ T cells and macrophages may contribute to suppression of delayed-type hypersensitivity during measles. The role of persistent MeV RNA in these PBMC defects has not yet been evaluated.

Th2 cytokine predominance produces an environment favoring B-cell maturation that facilitates the establishment of humoral memory important for lifelong protection from reinfection while depressing macrophage activation and induction of type 1 responses that may be required for combating new pathogens. Infection of monkeys with an IL-12-producing recombinant MeV increased production of IFN- γ and suppressed production of MeV-specific antibody, but there was no improvement in lymphocyte proliferation.²⁹⁵ Similarly, infection of cotton rats with an IL-4-producing recombinant MeV did not affect mitogen-induced lymphocyte proliferation.⁹⁶ These data suggest that the MeV-induced Th2 cytokine milieu may alter responses to other pathogens and thus contribute to increased susceptibility to infection, but do not explain the characteristic measles-induced defect in lymphoproliferation.

***In vitro* Infection of Immune Cells.** *In vitro* infection of leukocytes and leukocyte cell lines with MeV induces abnormalities of DC, monocyte/macrophage, B-cell, T-cell, and epithelial cell function. T-cell proliferation to mitogens and soluble antigens,⁴³⁷ cytotoxic function,⁹⁸ and B-cell production of immunoglobulin^{98,438} are suppressed by *in vitro* infection, and bone marrow stromal cells do not support development of hematopoietic stem cells.⁴²⁴ In addition, both B and

T cells can produce a soluble factor that inhibits proliferation of uninfected cells.^{692,755} These abnormalities may be relevant to immune suppression during measles, although some can be attributed to production of type I IFN in the MeV-infected cultures.

Infection of monocytes or macrophage-lineage cells *in vitro* stimulates production of IFN- α/β , inhibits production of TNF- α and IL-12, and may interfere with expression of peptide-loaded MHC class II complexes.^{344,393,619,793} Virus production decreases as macrophages mature.^{217,283} MeV infection of immature DCs induces maturation,^{642,653} but MeV replication impairs CD40L signaling necessary for terminal differentiation.⁶⁵³ Mannose receptor-mediated endocytosis is not affected.²⁶⁵

Monocytes and DCs exposed to MeV or N protein have impaired production of IL-12 but preserved or increased production of the regulatory cytokine IL-10.^{217,269,344,427,653} MeV interaction with CD46 increases nitric oxide and decreases IL-12 production,^{292,344} and interaction with DC-SIGN during infection of DCs increases IL-10 transcription by inducing acetylation of TLR-activated NF κ B subunit p65.²⁶³ Suppression of IL-12 production in response to TLR4 ligation is facilitated by H interaction with SLAM.²⁶⁹ N_{CORE} interacts with Fc γ R2 on B cells to inhibit antibody production *in vitro* and can trigger apoptosis.⁵⁷⁹ N_{TAIL} binds to thymic epithelial cells and activated T cells through an unidentified receptor to induce cell cycle arrest.⁵⁷⁹

Analysis of antigen-presenting function has shown that MeV-infected monocytes can present MeV, but not an unrelated antigen, to T-cell clones.³⁹² DC antigen-presenting function has been assessed primarily with the mixed leukocyte reaction (MLR) that measures proliferation of heterologous CD4+ T cells.^{642,681} The ability to stimulate this allogeneic T-cell response is lost after MeV infection, and the cells become apoptotic when co-cultured with T cells.^{217,265} MeV-exposed T cells are recruited into conjugates with DCs *in vitro* but have impaired clustering and maintenance of immune synapse proteins needed for sustained T-cell activation,⁶⁶⁶ in part due to sphingomyelinase activation and accumulation of ceramide.^{227,483,725}

The importance of the *in vitro* deficiencies identified in DC function is unclear. Microarray analysis of the transcriptional changes in DCs infected with MeV in comparison with other pathogens revealed that many of the changes postulated to be responsible for MeV-induced immune suppression were also induced by pathogens that are not associated with immune suppression⁸⁰⁸ and may be associated with IFN production. A vigorous MeV-specific cellular and humoral immune response is mounted to infection. This response results in rapid clearance of infectious virus, gradual clearance of viral RNA, and establishment of lifelong protective immunity.

Lymphocytes infected with MeV *in vitro* can be activated by mitogen but proliferate poorly because entry into S phase and progression through the cell cycle are impaired.^{57,225,437,440,496,641,789} Suppression of T-cell proliferation can also be induced without infection through direct inhibitory signaling to T cells by the viral glycoprotein complex of H and F₁-F₂ on virions or infected cells.^{170,360,634,642,766} This contact-dependent inhibitory signal prevents S phase entry of T cells for several days with accumulation of cells in the G₀/G₁ phase^{503,634,766} and is not dependent on cell death, membrane fusion, production of soluble inhibitors, or T-cell infection.^{170,188,505,641,765} Blocking the interaction of H with antibody to SLAM or CD46 does not interfere with

suppression of lymphocyte proliferation,¹⁹⁰ but antibody to H or F can reverse the inhibition.¹⁷⁰

MeV interaction with lipid rafts on the surface of T cells affects association of signaling molecules and their regulators with lipid rafts and interferes with T-cell activation of phosphatidylinositol 3 (PI3) kinase/Akt necessary for cell cycle progression in response to ligation of the T-cell receptor or the IL-2 receptor.^{30,33} Binding of the MeV glycoprotein complex to lipid rafts on resting T cells inhibits degradation of the cytoplasmic inhibitory protein Cbl-b and recruitment of Akt kinase and Vav.³³ In addition, induction of SIP110 phosphatase decreases availability of phosphatidylinositol-3,4,5-trisphosphate (PIP3) needed for phospholipid signaling.³² Determination of the relevance of this process to *in vivo* suppression of lymphoproliferation requires further study, but ongoing interaction of T cells in lymphatic tissue or in circulation with MeV-infected cells could induce this refractory state and result in suppressed proliferation in response to stimulation *ex vivo*.

Animal Models. Small animal models, primarily cotton rats and CD46 and SLAM transgenic mice, have also been used to study immunosuppression *in vivo* after MeV infection. Respiratory infection of cotton rats results in decreased proliferation of cultured T cells.⁵⁰⁴ Intravenously or intraperitoneally infected CD46 transgenic mice have impaired T-cell cytotoxicity and antibody production, and this is associated with increased susceptibility to bacterial infection.^{520,676} MeV infection of SLAM transgenic mice inhibits differentiation of DCs from bone marrow precursors through STAT1-independent, STAT2-dependent actions of type I IFN.^{96,270} N_{CORE} interacts with FcγRII on DCs to inhibit cutaneous hypersensitivity in mice.⁵⁷⁹ The relevance of these observations to the immune suppression that occurs during human infection is a matter of continued investigation.

AUTOIMMUNITY

An autoimmune demyelinating disease, postinfectious or acute disseminated encephalomyelitis (ADEM), is an important complication of measles⁴⁵⁷ (Fig. 36.14) and is associated with an immune response to myelin basic protein³³⁷ similar to that seen in animals with experimental autoimmune encephalomyelitis. The similarity of these diseases and lack of MeV in the brain have led to the current understanding that ADEM is an autoimmune disease³³⁷ induced during measles.

The mechanism of induction of autoimmune disease is not clear. Hypotheses have included altered presentation of myelin antigens due to MeV infection of oligodendrocytes, “molecular mimicry” of myelin antigens by MeV, and dysregulation of immune responses.^{294,328} There is little evidence for MeV infection of cells in the nervous system.^{230,337,460,460} The possibility of molecular mimicry between myelin basic protein

and an MeV protein has been explored. Neither cross-reactive antibodies nor cross-reactive T-cell clones have been identified in humans or rats with demyelinating disease induced in conjunction with MeV infection.³⁹⁷ Genetic susceptibility to ADEM has been postulated, but the numbers of patients studied have been insufficient to clearly identify a link between MHC antigens or other genetic markers and disease.³⁸³

Studies of immune regulation have shown that patients with encephalomyelitis differ from patients with uncomplicated disease by having a distinct pattern of immunologic abnormalities. IgE is more persistently elevated and soluble IL-2 receptor is lower.^{254,261} The timing of autoimmune disease suggests that immune dysregulation during measles may play a role in allowing activation and expansion of autoreactive lymphocytes.

Release and Transmission

Epidemiologic data suggest that infected individuals become infectious for nonimmune contacts a few days before the onset of the rash.³⁶² At this time virus can be cultured from the mucous membranes of the nasopharynx, conjunctivae, and mouth,¹⁸⁰ suggesting that the respiratory tract is the site of virus release. Multinucleated epithelial giant cells are readily demonstrated in nasal secretions and the conjunctivae during the prodrome and first days of the rash and are also shed into the urine.^{400,632} A recombinant virus that cannot infect epithelial cells is not shed from the respiratory tract of infected macaques, further suggesting that epithelial cells are the source of virus that is transmitted.³⁹⁰

Virulence

Strains of MeV can clearly differ in virulence because attenuated vaccine strains cause little disease in humans and wild-type strains cause measles. Sequences of these strains have been compared and several changes that may contribute to attenuation have been identified, but *in vivo* testing of virulence is difficult because of the lack of a good small animal model.⁷⁰⁷ Because adaptation of wild-type MeV to growth in Vero cells selects for a virus that no longer causes a rash in monkeys,^{43,365} many studies of virulence have focused on the sequence changes required for wild-type viruses to grow in Vero cells. Vaccine strains tend to use the CD46 receptor efficiently, while wild-type strains do not (determined in part by H aa residues at 390, 416, 446, 481, and 492), but this alone does not determine virulence.⁶⁹⁵ In addition to changes in H, attenuation and improved growth in Vero cells or chicken embryo fibroblasts are also associated with amino acid changes in the P/C/V, M, F, and L genes.^{42,169,346,489,656,697,698,704,706,788}

Virulence has also been assessed by the study of replication of MeV in human tissues explanted into culture or implanted into immunodeficient mice. In thymic implants wild-type

FIGURE 36.14. Time after infection of the occurrence of the three neurologic complications of measles: postinfectious or acute disseminated encephalomyelitis (ADEM), measles inclusion body encephalitis (MIBE), and subacute sclerosing panencephalitis (SSPE).

viruses grow more rapidly, to higher titer, and cause more extensive thymocyte apoptosis than attenuated strains.^{28,730} In human mononuclear cell implants and tonsil explants, wild-type strains grow better than vaccine strains.^{129,312} Attenuated vaccine strains infect naive T cells (express CD46, but little SLAMF7) more efficiently than virulent wild-type strains but infect B cells, macrophages, and NK cells less efficiently.¹²⁹ Again, the regions of the genome and the specific amino acid substitutions associated with these changes in replication and tissue destruction have not yet been defined.

Persistent Infection

MeV can establish persistent infection of cells *in vitro* and *in vivo*. A number of cell lines persistently infected with MeV have been established. Neurologic disease can be caused by persistent infection of neurons and glial cells.

Persistently Infected Cells in Culture

Replication of MeV usually causes death of cells in culture, but this is not necessarily the case *in vivo*. The elements determining persistent noncytopathic versus lytic infection are not completely understood, but properties of both the infected cell and the infecting virus contribute. Methods used to establish persistently infected cell lines include (a) passage of virus at high multiplicity with generation of DI particles,⁵⁹² (b) passage of infected cells in the presence of antibody,⁶¹² (c) cultivation of cells surviving lytic infection,^{204,612} and (d) co-cultivation of cells with MeV-infected brain cells from patients with SSPE or animals with persistent infection.⁴⁵⁰

Persistent noncytopathic infection is most easily established in neuronal cells but has also been established in lymphoid, epithelial, and glial cell lines.^{456,593} Cellular factors that influence persistence include expression of heat shock proteins, cyclic adenosine monophosphate (cAMP), IFN-inducible proteins, and altered regulation of lipid metabolism.^{456,593,597,640,700} Cellular protein synthesis is relatively unaffected by MeV infection, but specific cellular proteins (e.g., cell surface receptors) and functional responses (e.g., signal transduction, expression of transcription factors) may be altered, particularly in neural cells.^{54,210}

Strains of MeV and CDV differ in their ability to establish persistent nonlytic infection in the same host cell.²⁰⁴ Replication of variants likely to cause persistent infection is often temperature sensitive.⁵⁷⁴ Persistent infection is usually accompanied by a marked decrease in the amount of infectious virus released and by intranuclear and intracytoplasmic accumulation of nucleocapsids with decreased virus-induced cytopathic effect. Some cell lines produce no infectious virus,⁸⁷ and infection is maintained by passage of encapsidated viral RNA to daughter cells during cell division.

Limited expression of viral proteins on the surface of persistently infected cells has led to the suggestion that defects in synthesis of viral envelope proteins or processing of F may be an important component of persistent infection.^{450,797} Defects in glycoprotein expression may be due in part to limited mRNA production associated with steep transcriptional gradients and an increase in bicistronic messages.¹⁰⁷ However, mutations in these genes also lead to proteins with altered expression or function. For instance, defects in the M protein facilitate persistence and hinder association of N with the viral glycoproteins.⁵³⁵

Subacute Sclerosing Panencephalitis

SSPE is a rare (approximately 1 in 10,000) late complication of measles for which the pathogenesis remains poorly understood.^{61,702} The route of virus entry into the CNS is unknown, but infection of cerebral endothelial cells is one possibility.^{197,358} SSPE is most likely to occur when MeV infection occurs under the age of 2 years when the immune system is immature and maternal antibody may still be present.^{61,152,272,326,455,458}

There is no clustering of cases to suggest that the wild-type virus causing the initial infection is different from the virus causing uncomplicated disease. Extensive sequence analysis of viral RNA from various parts of the brain in SSPE suggests that the virus in the CNS is clonal,³⁷ implying that virus entered the brain at one time (presumably during the original acute infection), was not cleared, and then gradually spread throughout the nervous system. The typical incubation period is 7 to 10 years⁴⁵⁸ (Fig. 36.14). There may also be a genetic predisposition to developing persistent infection.^{323,324}

STUDIES OF BRAIN AND BRAIN-DERIVED CELL LINES

At the time that neurologic symptoms occur, neurons and glia contain nuclear and cytoplasmic viral inclusion bodies, antibody responses to virus are vigorous and evident both in serum and CSF, and there is an extensive mononuclear inflammatory reaction in the CNS.^{80,142,287} Both white matter and gray matter are affected.¹⁴² No virus is seen budding from the surface of infected cells, and nuclear inclusions are filled with “smooth” nucleocapsids.^{171,287} The cytoplasm contains “fuzzy” nucleocapsids that extend into neuronal processes, suggesting that virus can spread within the CNS by synaptic transmission of the ribonucleoprotein from cell to cell, a process that has been observed both *in vivo* and *in vitro*.^{175,177,382,631} Neurokinin-1, the substance P receptor, may interact with the MeV F protein at the synapse for neuronal transmission.⁴¹⁹ In CDV infection, astrocytes participate in rapid noncytolytic spread from cell to cell to establish persistence.⁷⁸⁷

Alterations in any of the MeV envelope proteins that in some way interfere with assembly and budding of infectious virus can be associated with persistent infection and SSPE.^{38,108,110,635} Extensive sequence analysis of viral RNAs from tissue has shown that SSPE viruses are related to wild-type strains circulating at the time of the primary infection but frequently have mutations in the viral genes encoding the M, F, and H proteins.^{38,110,335,635}

In general, expression of M, a protein particularly important for assembly of infectious virus, is low.³⁹⁵ This may be due either to lack of M protein synthesis or instability or mislocalization of the synthesized protein.^{334,657,682} A variety of defects have been encountered in the mRNAs encoding M extracted from SSPE brain.¹¹⁰ Mutations occur throughout the gene, and the frequent U-to-C sequence changes noted in some viruses may suggest mutation of double-stranded RNA in persistently infected cells by adenosine deaminase (biased or A/I hypermutation).^{104,783} M transcripts often lack initiator AUGs necessary for expression and, when expressed, the proteins have defects in binding to viral nucleocapsids and in down-regulating transcription.^{290,693} H proteins are often defective in intracellular transport and protein–protein interactions important for cell–cell fusion.¹⁰⁸ Truncations, mutations, and deletions in the cytoplasmic domain of F are almost universal and some enhance fusion and thus interfere with virus budding.^{35,108,635}

IMMUNE RESPONSES

The possibility that the development of SSPE is due to an immune defect has been investigated. The antibody response to MeV is accentuated with significant production of MeV-specific antibody by plasma cells residing in the CNS and present in CSF.^{85,526} Levels of CSF immunoglobulin, much of which is MeV specific, are elevated.^{195,724} Antibody produced in the CNS is of restricted heterogeneity, leading to the appearance of oligoclonal immunoglobulin bands on electrophoretic analysis of CSF. Antibodies against the N and P proteins present in the ribonucleoprotein complex are particularly abundant, and antibody against the M protein is particularly deficient.²⁷¹

Antibody to MeV has been postulated to play a role in establishing persistent CNS infection either through alteration of the induction of the primary immune response at the time of infection⁵⁷⁷ or through modulation of infection once virus is in the nervous system.²¹⁸ Treatment with antibody after intracerebral infection of small mammals with neuroadapted strains of MeV attenuates acute disease but increases the incidence of subacute or chronic encephalitis.⁵⁷⁶ Cases of SSPE have been associated with passive transfer of immune globulin, and persistent infection has been induced experimentally by passive transfer of antibody.⁵⁷⁷

Studies of cellular immunity have been less extensive. MeV-specific lymphoproliferation is not impaired, but MeV-specific cytotoxic T-cell activity and production of IFN- γ are decreased compared with healthy seropositive individuals.^{158,275} General measures of cellular immunity, such as skin test responses to various recall antigens and proliferative responses to mitogens, are normal. The mononuclear inflammatory response in the brain includes CD4+ and CD8+ T cells, as well as monocytes and Ig-secreting B cells.^{20,195} Class I and class II MHC expression is increased in brain, and β_2 -microglobulin, soluble IL-2 receptor, and soluble CD8 are increased in CSF.⁴⁴⁸ Thus, there is no evidence for a global defect in immune responses, but these immune responses are ineffective in clearing virus from the CNS.

Other Chronic Diseases

In addition to a clear role in SSPE, MeV in combination with genetic factors has also been implicated in the pathogenesis of Paget disease,^{216,376,673} otosclerosis,^{442,645} chronic active hepatitis,⁵⁹⁶ and multiple sclerosis.¹⁵ For most of these diseases an etiologic link to measles is controversial^{282,434,453,575,777} and for none has a definitive role for MeV been identified.

Veterinary Correlates

Canine Distemper

Canine distemper was first described by Carre in 1905 as an infectious disease of young dogs associated with gastroenteritis, pneumonitis, conjunctivitis, and encephalomyelitis.⁹⁴ The disease has been recognized for centuries and epidemics were recorded in the 17th century.⁷⁰ Canine distemper was shown to be of viral etiology in 1926,³⁷⁸ and the virus was isolated in primary canine kidney cells in 1959.⁵⁹⁸ CDV causes disease in both domestic dogs and wild canids.^{16,245,465} Through adaptive mutation in the H gene, CDV has acquired a broader host range than many morbilliviruses and can cause disease in monkeys and all families of terrestrial carnivores.^{149,436,465,571} Canine distemper has many similarities to measles in humans, but infection of the CNS and neurologic disease are more common

with glial cells as a primary target.⁷⁴⁰ CDV is spread by aerosol and the disease is characterized by fever, coryza, conjunctivitis, gastroenteritis, and pneumonitis.¹⁷³ Using ferrets as a model system, researchers showed that CDV appears first in bronchial lymph nodes followed by a cell-associated viremia and spread to multiple lymphoid organs.⁷⁴⁷ Later, infection spreads to epithelial tissues and enters the brain by infecting endothelial cells or through infiltration of infected monocytes.³⁴ Like measles, canine distemper is associated with profound short- and long-term immune suppression, and much of the mortality is due to secondary infections.

Dogs, ferrets, and lions may develop neurologic complications characterized by gait abnormalities and seizures.¹⁷³ Neurologic disease is most common in young animals³⁷² and can occur either early after infection or 3 to 4 weeks later associated with demyelination.⁷⁴⁰ Persistence of virus in neural cells and in epithelial cells of the feet leads to chronic diseases known as old dog encephalitis and hard pad disease.^{21,371} Some cases of old dog encephalitis have defective virus, with intranuclear inclusions in the CNS co-existing with high levels of antiviral antibody, features in common with SSPE.

Rinderpest

Rinderpest virus was first recognized as a distinct clinical entity causing severe gastroenteritis in cattle during a 4th-century European epizootic.⁵⁵³ The causal agent of this disease was reported to be filterable in 1902⁴ and was isolated in bovine embryonic kidney cells in 1957.⁵⁵⁴ RPV has been an important veterinary pathogen⁵¹ and causes a highly contagious disease of ruminants and swine characterized by inflammation, hemorrhage, necrosis, and erosion of the gastrointestinal tract.⁴ RPV replicates in lymphocytes and macrophages, leading to lymphoid necrosis, and in epithelial cells of the gastrointestinal, respiratory, and urinary tracts and endocrine and exocrine glands, but not the brain or spinal cord.^{687,780} Vaccination has recently succeeded in eradicating this disease from its last sites in Africa.^{301,467}

Peste des Petits Ruminants

Peste des petits ruminants virus (PPRV) causes an economically important disease of sheep, goats, buffalo, and camels in Africa, the Middle East, and Asia.^{157,377} The disease was first discovered in West Africa in 1942 and is characterized by fever, erosive stomatitis, pneumonitis, diarrhea, and lymphoid cell depletion.⁴⁷⁰ PPRV replicates in epithelial cells, pneumocytes, macrophages, and lymphocytes.³⁷⁵ PPRV is related to RPV⁴¹ (Fig. 36.1), and four lineages are recognized. Disease in northern and eastern Africa is increasing, perhaps due to the introduction of a more virulent Asian strain into the region.³⁷⁷

Morbillivirus Infections of Aquatic Mammals

In 1987, an epizootic of respiratory disease with high mortality due to secondary infections occurred in seals in the Baltic and North Seas.⁷⁴⁵ Serology suggested infection with a morbillivirus related to CDV, and the causal agent, phocid distemper virus (PDV), was isolated in 1988 (Fig. 36.1).³⁵¹ Infection has since spread to otters in the Pacific Ocean and seals along the East Coast of the United States.^{241,545} The disease is characterized by fever, nasal and ocular discharge, and severe respiratory, gastrointestinal, and CNS symptoms. In the CNS there is neuronal infection with inflammation.⁶⁸³ Disease is complicated by

a variety of secondary viral, bacterial, and parasitic infections, suggesting the type of immune suppression seen in measles and canine distemper virus.⁵²² Similar epizootics of severe respiratory disease were subsequently recognized in porpoises and dolphins, and distinct morbilliviruses (PMV and DMV, now grouped together as cetacean morbillivirus [CeMV]) were isolated from these animals⁵² (Fig. 36.1). PDV and CeMV cause giant cell pneumonia, encephalitis, and lymphoid depletion with virus demonstrable in lung, brain, spleen, and bladder.¹⁶¹

Experimental Infection in Animals

Nonhuman primates can be infected naturally or experimentally with MeV and provide the only experimental model for the pathogenesis of human disease. Small laboratory mammals generally are not susceptible to wild-type strains of MeV, although replication has been reported in the respiratory tract of cotton rats⁷⁸⁵ and in transgenic mice expressing the human MeV receptor CD46⁴²¹ and/or SLAM.⁶⁶³ Several neurotropic strains of MeV have been developed by repeated intracerebral passage in hamsters, mice, and rats. These strains do not produce acute disease similar to that seen in humans, but rather serve as models for neurologic diseases such as SSPE.

Nonhuman Primates

Natural MeV infection occurs only in humans. However, a number of species of monkeys are susceptible to measles and can contract the disease through contact with humans.^{583,735} Experimentally, monkeys can be infected by intranasal, intratracheal, or subcutaneous inoculation.^{29,735} Disease is generally similar to that seen in humans, and when deaths occur they are often caused by secondary infections.⁵⁸³ Rhesus and cynomolgus macaques have served as animal models for studies of measles pathogenesis, immune suppression, virus virulence, response to vaccines, and protective immunity.^{29,178,182,389,402,439,441,528,735}

Marmosets and tamarins are also susceptible to natural and experimental MeV infection by the respiratory route but develop a fulminant disease with high mortality characterized by interstitial pneumonitis, gastroenterocolitis, and bacteremia.⁴⁰⁹ Infection with vaccine strains produces little disease.⁴⁰⁹ Intracerebral inoculation with the most virulent strains of MeV produces encephalitis, while attenuated strains do not.¹¹

Cotton Rats

The respiratory tract of cotton rats (*Sigmodon hispidus*) can be infected with vaccine and wild-type strains of MeV.^{544,785} Virus replicates in the lungs and wild-type strains can spread to mediastinal lymph nodes and induce immunosuppression as measured by decreased proliferation of spleen cells to mitogen stimulation.⁵⁴⁴ Cotton rats have been used for studies of pathogenesis, immune suppression, vaccine-induced immune responses, and protection from infection.^{96,359,463,544,569,785,786}

Rats

The hamster neurotropic (HNT) strain of MeV can infect laboratory rats after intracerebral inoculation. The CAM strain of MeV was adapted by serial passage to replicate in rat brain and causes fatal encephalitis in newborn rats.³⁹⁹ The type of disease produced in older rats is determined by the strain of rat. In Brown Norway rats, 10% to 20% develop acute encephalitis and there is no late disease in survivors. In Lewis rats, 80% to 90% develop acute fatal encephalitis and the rest develop sub-

acute disease. Infectious, cell-free virus can be recovered during acute, but not subacute, disease.³⁹⁹ Unlike mice, transgenic expression of human CD46 does not increase the permissiveness of rats for MeV infection.⁵⁰⁶

Rats have been used to identify determinants of neurovirulence and the role of the immune response in MeV-associated neurologic disease and persistent infection.^{416,459,581} Acute encephalitis in newborn rats can be modulated by passive transfer of antibody to the H protein that results in persistent infection and a late onset of disease.³⁹⁶ Features of subacute disease that are similar to SSPE include an inability to recover virus by routine methods, restricted expression of MeV envelope protein mRNAs in the brain, and intrathecal synthesis of oligoclonal MeV-specific antibody.^{399,638} Demyelination is not a feature of subacute encephalitis; however, demyelinating disease can be more easily induced in previously infected animals.³⁹⁸

Hamsters

Newborn hamsters are susceptible to CNS infection with wild-type, vaccine, and SSPE strains of MeV; develop hyperirritability leading to death within a few days; and have been used to assess determinants of neurovirulence.^{36,329} Brains from these young animals show giant cell encephalitis with intranuclear and intracytoplasmic inclusion bodies and a polymorphonuclear inflammatory response.⁷⁵³ Older animals develop myoclonus with infection of cortical, thalamic, and hippocampal neurons without giant cell formation.^{691,753} Ependymal infection may lead to hydrocephalus.³²⁹ Cell-free virus can be easily recovered from the brains of newborn, but not older, hamsters.⁹⁰ Demyelination is uncommon,⁷⁵³ but some hamsters inoculated as newborns with the LEC SSPE strain develop myelitis weeks later.⁹⁵

Mice

Several strains of MeV have been adapted to grow in the brains of newborn mice and cause fatal disease after intracerebral, but not peripheral, inoculation.^{319,501} Histopathology and immunocytochemical staining show neuronal and glial infection and giant cell encephalitis.^{257,410,501} Maturation of CNS cells converts the production of MeV from the infectious form in newborn mice to a defective form in weanling mice.^{257,286} In weanling mice, MeV antigen-positive neurons have only smooth nucleocapsid structures and no detectable H, F, or M proteins.^{286,410} Disease consists of hyperexcitation and seizures associated with production of excitotoxic amino acids and destruction of pyramidal cells in the hippocampus that can be prevented by administration of glutamate receptor antagonists.^{257,410} The genetic background of the mouse influences susceptibility,⁷⁶³ with C3H/He mice most susceptible and SJL mice most resistant.⁵⁰¹ Mice with deficiencies in cellular immunity are more susceptible than immunocompetent mice.^{207,727}

A number of investigators have produced mice engineered, either by grafting human cells or by transgenic expression of human genes, to provide better murine systems for studying measles pathogenesis. Mice with severe combined immunodeficiency have been grafted with human PBMCs³¹⁵ or implanted with human fetal thymus and liver.²⁸ In thymic implants MeV shows strain-specific differences in virus growth and thymocyte apoptosis that have been useful for assessing virulence and determinants of replication *in vivo*.^{28,730,731} Immunologically

normal mice with transplanted human leukocytes develop graft versus host disease and can also be infected with MeV.³¹⁵

Transgenic mice expressing human CD46 or SLAMF have been produced using genomic DNA or complementary DNA (cDNA) with promoters designed to provide generalized or cell type-specific expression of the receptor transgene.^{270,421,536,663,768} In general, only low levels of infectious virus can be recovered from the mice and this is age dependent, with neonatal mice much more susceptible than older mice.⁵³⁶ MeV replication in transgenic mice is enhanced by the absence of components of the innate or adaptive immune response,^{421,514,663} but blocks to MeV replication in mice are at multiple levels.⁷⁴⁴ These mice and cells from these mice have been used for studies of pathogenesis, virulence, immunosuppression, and CNS infection.^{205,268,270,366,518,649,650,706}

Ferrets

Intracerebral inoculation of ferrets with cells infected with certain SSPE strains of MeV causes acute encephalitis.³⁴⁷ Subacute or chronic encephalitis is established if animals are immunized prior to intracerebral injection with infected cells.⁷²⁰ Pathologic and clinical features in animals with chronic disease resemble SSPE with cerebral inflammation, gliosis and intranuclear inclusion bodies, electroencephalographic changes, bound immunoglobulin in brain, and high titers of antibody to MeV in serum and CSF.^{347,720}

EPIDEMIOLOGY

Classic Measles

In the Absence of Vaccination

The study of island populations was important in establishing many of the principles of measles epidemiology. Pioneering observations on the transmissibility, incubation period, and lifelong immunity of measles were made by Panum during the 1846 epidemic in the Faroe Islands.⁵³⁰ Measles is one of the most infectious of communicable diseases. It is estimated that 76% of household exposures of susceptible persons lead to measles²⁹⁹ and that the reproductive number (R_0), or average number of secondary cases produced by an infectious individual in a totally susceptible population, is approximately 12 to 18.^{466,694} Transmission is most efficient through direct exposure to an infected symptomatic individual, but MeV can survive for hours in respiratory droplets, and direct contact is not required.¹¹⁹ Individuals are most infectious from 4 to 5 days before through 4 days after the appearance of the rash.¹²¹

There is no animal reservoir or evidence of latent or epidemiologically significant persistent infection. Therefore, maintenance of MeV in the human population requires a continuous supply of susceptible individuals. Because older members of a community are immune through previous exposure to the virus, endemic measles is primarily a disease of childhood. If the population is too small to establish endemic transmission, the virus cannot be maintained.⁶⁶ Mathematical calculations and studies of islands and cities with populations of different sizes have shown a requirement for a population of 250,000 to 500,000 to establish measles as an endemic disease.^{67,350} This is approximately the population of the earliest urban civilizations in ancient Sumaria around 3000 BCE where measles is postulated to have emerged.

In large population centers, measles is endemic with occasional epidemics as the numbers of susceptible individuals increase. These epidemics spread in waves from large cities to smaller cities and then to rural areas over time.²⁵² In temperate climates measles is more frequent in the winter and early spring. The frequency of epidemics is determined by numbers of susceptible individuals, the duration of infectiousness, and patterns of population mixing.³⁵⁰ The size of the population is also a primary determinant of the age of seroconversion. The average age of infection is earlier in urban than in rural areas in both developed and developing countries.¹³⁹ In countries with high birth rates, infection occurs at an early age. Very young infants are protected from measles (and from response to vaccine) by maternal antibody.⁹ The duration of protective antibody in the infant is dependent on the level of maternal antibody. The source of maternal immunity (vaccine vs. natural measles), gestational age, and presence of maternal infection (e.g., human immunodeficiency virus [HIV], malaria) are determinants of the amount of antibody passively transferred and, therefore, the length of time required for initial levels of antibody to decay to the point that an infant will become susceptible to measles.⁹¹ In small isolated populations measles epidemics are controlled by extinction and chance reintroduction of the virus that leads to infection at older ages on average.^{121,586}

Effect of Vaccination

Immunization alters the epidemiology of measles by reducing the susceptible individuals in the population. In countries with high rates of vaccination, the average age for measles is increased because herd immunity reduces transmission and indirectly protects children from infection. Vaccination also lengthens the interepidemic period.¹³⁹ When outbreaks occur in areas of sustained high vaccine coverage, an increasingly large portion of the cases will be in older individuals who are susceptible due to primary or secondary vaccine failure. In contrast to prevaccination populations, outbreaks are increasingly likely to be local and dependent on social networks.⁷⁵⁴ Because of the infectiousness of MeV and the high R_0 , it is estimated that 95% or more of the population needs to be immune to interrupt endemic transmission.²²⁸ However, even highly immunized populations are vulnerable to localized outbreaks associated with importation from areas where measles remains endemic.^{228,607} These risks are increased in communities that include individuals who refuse vaccination for philosophical or religious reasons.²⁰²

Molecular Epidemiology

Sequence analysis of the variable C-terminus of the N (N_{TAIL}), P, and H genes has been useful for identification of genotypes and analysis of the molecular epidemiology of measles.⁶⁰⁵ Several lineages of MeV that have characteristic temporal and geographic distributions have been identified.^{595,604} Some are localized to specific regions of the world and some are extinct, but most are widely distributed. Currently 8 distinct clades with 24 genotypes are recognized (see section on antigenic composition and strain variation) (Fig. 36.9). Assembly of this increasingly large database of MeV genotypes has aided in the identification of global measles transmission pathways.^{353,606} Identification of the source of the MeV-causing disease in a particular location has become increasingly important as control programs are implemented, and identification of cases as imported or indigenous is necessary.⁶⁰⁷

Subacute Sclerosing Panencephalitis

SSPE occurs preferentially in boys from rural areas with a history of measles at an early age.^{272,326,458} In developing countries with high birth rates, measles often occurs in young infants,^{247,272,472,475} and these countries have a high burden of SSPE.^{426,614,702} This is further exacerbated when there is a high prevalence of HIV infection because children of HIV-infected mothers are more likely to acquire measles at an early age.^{179,475} Several studies have identified exposure to birds as a risk factor, but this relationship has not yet been explained.²⁷² The incidence has decreased dramatically with the introduction of measles vaccination,^{61,92} and there is no evidence that the vaccine virus can cause SSPE.⁴⁵⁸

CLINICAL FEATURES

Classic Measles and Its Complications

Measles has an incubation period of 10 to 14 days spanning the time from exposure to the appearance of clinical disease (Fig. 36.11). The first prodromal symptoms of measles are fever, malaise, and anorexia followed by cough, coryza, and conjunctivitis. The prodrome lasts 2 to 3 days, and during this time small bright red spots with a bluish-white speck at the center, Koplik spots, may become visible on the buccal mucosa, providing early diagnostic evidence of measles.^{368,721} The prodrome ends as the maculopapular rash appears, first on the face and behind the ears and then on the trunk and extremities (Fig. 36.10). It begins to fade within 3 to 4 days. In malnourished children the rash may desquamate.⁴⁶⁹ Generalized involvement of lymphoid tissue may result in lymphadenopathy, mild splenomegaly, and appendicitis. In uncomplicated measles clinical recovery begins soon after appearance of the rash.

Respiratory Disease

The prominent respiratory symptoms are manifestations of diffuse mucosal inflammation in response to widespread infection of epithelial cells. Interstitial pneumonitis due to MeV replication and inflammation in the lower respiratory tract is common in uncomplicated disease but frequently is detectable only by x-ray or by measuring the alveolar–arterial oxygen gradient.^{251,285} Pneumonitis is more likely to be clinically severe during pregnancy.¹² Symptomatic giant cell pneumonia is seen primarily in immunocompromised individuals.^{183,429} Most of the severe pneumonia that complicates measles and leads to chronic pulmonary disease is caused by secondary bacterial and viral infections.^{56,251} Other common respiratory complications caused by secondary infections are otitis media and laryngotracheobronchitis.⁵⁶ In addition to increasing susceptibility to new infections, previously latent viral and bacterial infections may be reactivated.^{121,690}

Gastrointestinal Disease

MeV replication in the liver, particularly the bile duct epithelium, is common in all ages, but clinically evident hepatitis is most frequent in adults.^{235,387} Diarrhea is a common complication of measles, particularly in young patients requiring hospitalization.²⁵⁰ Many epithelial surfaces are infected with MeV and this may lead directly to gastrointestinal symptoms. However, diarrhea is frequently associated with secondary bacterial

and protozoal infections²⁵⁰ that compound the borderline nutritional status of young children in developing countries.

Myocardial Disease

Electrocardiographic abnormalities, including prolongation of the P-R interval and ST-segment and T-wave changes, can be detected in 20% to 30% of children with uncomplicated measles.²³⁹ However, symptomatic cardiac disease is uncommon and is most often related to transient conduction abnormalities. In autopsy studies, myocardial and pericardial lesions are usually attributable to systemic bacterial infections.

Neurologic Disease

There is little evidence that the brain parenchyma is an important target tissue for MeV replication during acute disease in immunologically normal individuals.^{446,460} However, apparently uncomplicated measles is frequently accompanied by a CSF pleocytosis and changes in the electroencephalogram,^{234,274} suggesting the possibility of CNS infection. The occasional appearance of slowly progressive neurologic disease (measles inclusion body encephalitis [MIBE]) in immunosuppressed individuals^{8,214,484} and the occurrence of late neurologic disease (SSPE) in immunologically normal individuals infected at a young age (Fig. 36.14) attests to the ability of MeV occasionally to enter the brain and replicate in neurons and glial cells.

ADEM complicates 1 in 1,000 cases of measles, with the highest attack rate in children older than the age of 5 years,⁴⁵⁷ and usually occurs within 2 weeks after the onset of the rash.⁴⁰⁶ (Fig. 36.14). The disease is characterized by an abrupt onset of fever and obtundation, accompanied by seizures and multifocal neurologic signs. The majority of survivors have neurologic sequelae.^{337,406} Pathologic studies show that this is a perivenular demyelinating disease, not inclusion body encephalitis like MIBE and SSPE.⁴⁰⁶ The pattern of perivenular inflammation and demyelination suggests that it is immunologically mediated.^{230,799} There is little evidence for virus in the brain as assessed either directly by virus isolation or detection of viral antigen or RNA^{230,460} or indirectly by the appearance of MeV-specific antibody in the CSF.³³⁷ There is, however, the induction of an autoimmune response to myelin protein similar to that seen in animals with experimental autoimmune encephalomyelitis and humans with Semple rabies vaccine-induced encephalomyelitis.^{78,162,337,380}

Eye Disease

Measles is considered to be an important cause of childhood blindness associated with corneal lesions. In areas of vitamin A deficiency, the two problems are synergistic and corneal ulceration resembling keratomalacia is a frequent complication of measles.⁶²⁰

Determinants of Morbidity and Mortality

Measles remains one of the most important causes of child morbidity and mortality worldwide.^{473,494,781} Predictors of poor outcome are severe lymphopenia and poor antibody response.^{132,770} Mortality is highest at the extremes of age, in girls, in those with low socioeconomic status, and in those without access to medical care.^{121,163,226,599} Mortality is also increased in malnourished individuals⁴⁸ and secondary cases in a household.^{1,369} Malnutrition affects the immune responses to MeV, impairs virus clearance, and may lead to lower rates of

diagnosis.^{141,564} Vitamin A is a particularly important nutrient influencing outcome.⁴⁸ Low serum retinol is common in severe measles due either to prior dietary deficiency or to impaired mobilization from hepatic stores.^{48,89} Case-fatality rates range from 0.1% in places with good access to medical care to 6% in developing countries and up to 25% in refugee camps and virgin populations.^{139,247,471,494,655,781}

Atypical Measles

A severe form of measles with unusual clinical features was seen in individuals who had previously received an inactivated measles vaccine used in the mid-1960s. Atypical measles differs from typical measles by having higher and more prolonged fever, unusual skin lesions, and severe pneumonitis.^{221,486} The rash often is accompanied by evidence of hemorrhage or vesiculation and begins on the extremities and spreads to the trunk. Pneumonitis is associated with distinct nodular parenchymal lesions and hilar adenopathy.^{251,798} Abdominal pain, hepatic dysfunction, headache, eosinophilia, pleural effusions, and edema are also described. Cases of atypical measles were reported up to 16 years after administration of the inactivated vaccine. Administration of live virus vaccine after two to three doses of killed vaccine did not eliminate subsequent susceptibility to atypical measles and was often associated with severe local reactions.^{88,117,220}

Hypotheses about the pathogenesis of atypical measles included an abnormally intense cellular immune response,²²⁰ an inability of the inactivated vaccine to induce local respiratory tract immunity,⁵⁸ and a lack of production of antibody to F, which allowed virus to spread from cell to cell despite the development of antibody to H.^{452,507} In rhesus macaques the formalin-inactivated vaccine induces transient neutralizing and fusion-inhibiting antibodies, but there is a poor T-cell response and antibodies induced do not mature. Subsequent infection with MeV induces an anamnestic response of low-avidity antibody that cannot neutralize wild-type virus. This leads to immune complex deposition, vasculitis, and pneumonitis.⁵⁵⁹

Measles in the Immunocompromised Host

Children with hypogammaglobulinemia appear to recover uneventfully from MeV infection, while those with deficiencies in cellular immune responses may not.²⁴⁴ Virus clearance is delayed,⁵⁴² and two types of progressive disease, giant cell pneumonia and MIBE, may complicate infection, often in the absence of the typical rash or other characteristic features of measles.^{84,183,429}

Giant cell pneumonia is characterized by increasing respiratory insufficiency beginning 2 to 3 weeks after a history of exposure to measles. Virus can be isolated from lung tissue and bronchial and nasopharyngeal washings.¹⁸³ Pathology shows multinucleated epithelial alveolar and bronchiolar giant cells with intranuclear and intracytoplasmic inclusion bodies.²² There is often evidence of systemic disease with giant cells visualized in multiple organs.^{22,183}

MIBE occasionally accompanies giant cell pneumonia³⁴⁰ but is more often present as an isolated primary manifestation of progressive MeV infection in immunocompromised adults and children.^{8,214,310,484,782} Neurologic disease usually becomes evident within 6 to 12 months after exposure to measles (Fig. 36.14). Initial signs and symptoms include altered mental status, focal seizures or epilepsy partialis continua,

and occasionally blindness or hearing loss.^{6,8,273} The course is typically rapid with progression to coma and death within weeks to months.⁴⁸⁴ Pathology shows gliosis with inclusions in glial cells and neurons.²⁴⁶ Giant cell formation is unusual and little inflammation is present.^{6,484} MeV protein and RNA are abundant and detectable by immunocytochemical staining or *in situ* hybridization. MeV can occasionally be recovered from brain, but the virus is usually defective, as it is in SSPE.^{6,39,601} Viral nucleocapsids without budding particles are seen intracellularly by electron microscopy.^{6,601} The mRNAs for genes encoding the H, M, and F envelope proteins are reduced, and these proteins are often undetectable.^{39,106} MIBE may be fundamentally similar to SSPE, but clinical symptoms are manifested earlier after infection and are more rapidly progressive in the absence of an immune response.⁶⁰¹

Subacute Sclerosing Panencephalitis

SSPE most commonly occurs in individuals younger than the age of 20 who present many years after measles with neurologic disease. The average time to onset of SSPE after measles is 6 to 10 years (Fig. 36.14) but ranges from 1 to 24 years.^{92,458} The onset is insidious and the diagnosis is often not suspected early in disease.^{298,565} The typical presentation is with mental deterioration and personality changes (stage I). Subsequently, there is myoclonus and often seizures (stage II) followed by progressive neurologic deterioration marked by rigidity (stage III), optic atrophy, akinetic mutism, and coma (stage IV).³²⁷ Death occurs within months to years after onset.²¹⁵ Antibody to MeV is elevated in both serum and CSF, and inclusions are present in glial cells and neurons.²⁸⁷ Perinatal infection can be associated with SSPE that has an accelerated onset and a fulminant course.^{92,672}

DIAGNOSIS

The classical clinical features of measles—Koplik spots, fever, erythematous maculopapular rash, coryza, cough, and conjunctivitis—are generally sufficient to make the diagnosis, especially in the setting of a community outbreak, but laboratory confirmation should be obtained. The clinical case definition for measles includes (a) a generalized maculopapular rash of 3 days or more; (b) fever of 38.3°C (101°F); and (c) one of the following: cough, coryza, or conjunctivitis.¹¹¹ However, not all of these signs and symptoms may be present in measles and many are shared with other diseases. The differential diagnosis includes all causes of rash and fever including scarlet fever, rubella, alphavirus infection, parvovirus B19, human herpesvirus-6, human herpesvirus-7, meningococcemia, Kawasaki disease, toxic shock syndrome, and dengue.^{81,563} Fever and/or rash may be absent during measles in very young infants, immunocompromised patients, malnourished children, and previously immunized individuals.^{176,564}

Laboratory diagnostic procedures consist of isolation of virus; direct detection of the virus, viral RNA, or viral antigens in secretions; detection of IgM or low-avidity IgG antibody by enzyme immunoassay (EIA); or documentation of seroconversion using hemagglutination inhibition (HI), complement fixation (CF), virus neutralization, or IgG-specific EIA on serum taken during the acute and convalescent phases of disease. In immune-compromised patients, the diagnosis is difficult, often

not suspected, and usually dependent on biopsy to detect MeV in tissue.^{8,484,562}

Isolation or Detection of Virus

Virus can be cultured from PBMCs, respiratory secretions, conjunctival swabs, and urine, but culture is rarely used as the means of diagnosing acute disease. Cell lines vary in their susceptibility to infection by wild-type strains, with human cord blood leukocytes, the COBL-a cord blood T-cell line, marmoset B95-8 or B95a cells, and Vero cells expressing SLAM being most sensitive.^{211,364,365,521} Epithelial cells from the nasopharynx, buccal mucosa, conjunctivae, or urine can be used for direct cytologic examination for giant cells and inclusions and for antigen detection.^{400,677} Generally, the most useful antibody for staining is one directed to N because this protein is most abundant in the infected cell and N antibody reactivity is retained using a wide variety of fixation methods.⁶⁷⁷ Direct examination for virus is of particular importance for diagnosis in immunocompromised individuals where antibody responses may not be present. The detection of MeV RNA by RT-PCR using primers targeted to highly conserved regions of the N, M, or F genes has been successfully applied to a variety of clinical samples^{7,198,317,542,719} and to most morbilliviruses.^{248,394,668}

Detection of Antibody

The clinical diagnosis of measles is most often confirmed by serology. Samples ideally consist of acute and convalescent serum pairs, but detection of MeV-specific IgM in serum or saliva or low-avidity IgG in serum is diagnostic and may require only a single sample.^{81,206,317,726} IgM antibody appears at the time of the rash and can be detected by 3 days and for up to 4 weeks after the onset of the rash in most individuals.²⁸¹ MeV-specific IgG peaks approximately 2 weeks later and gradually increases in avidity. EIA allows for differential detection of IgM and IgG and is widely used because of its convenience. Plates may be coated with lysates of MeV-infected cells or with recombinant MeV proteins.^{74,314}

The HI test detects antibody to HA and correlates well with the neutralization test. The major limitations of the HI test are the requirement for fresh sensitive monkey erythrocytes, the difficulty of producing sufficient antigen for large numbers of tests, and the possible presence of nonspecific HA inhibitors in serum. The CF test has also been used to determine measles immunity, but titers are less stable over time. Neither of these tests is in common use. The virus plaque reduction neutralization assay remains the standard against which other tests are measured. It is more sensitive than HI or EIA tests^{10,126} and provides the best correlate for protection from infection¹²⁰ and therefore remains the best measure of response to vaccination.⁹

PREVENTION AND CONTROL

Treatment

There is no standard antiviral treatment for measles. Ribavirin inhibits MeV replication *in vitro*; however, immunocompromised patients with pneumonitis have shown no clear evidence of improvement after treatment with aerosolized ribavirin. Newer approaches to therapy that are effective *in vitro* include nonnucleoside polymerase inhibitors^{771,796} and fusion inhibitors.⁵⁶⁸ Administration of high doses of vitamin A dur-

ing acute measles decreases morbidity and mortality even in the absence of clinical evidence of vitamin A deficiency by an unknown mechanism.^{48,221,316} In areas of vitamin A deficiency and xerophthalmia, supplementation prevents blindness due to measles-induced corneal destruction. The World Health Organization recommends two doses of vitamin A for all children with measles.⁷⁷⁴

Numerous therapeutic agents, including amantadine, IFN, isoprinosine, ribavirin, and transfer factor, have been used for the treatment of SSPE. Evaluation of the efficacy of any of these regimens is difficult because the disease is rare, the course is variable, reports are anecdotal, and the benefits are at best short term.²⁶⁶

Vaccination

History

The earliest attempts at vaccination against measles by Home in 1749 were based on the principles of variolation²⁹⁷ with the reasoning that introduction of disease through the skin would lessen the effects on the lung. "Morbillization" was in general unsuccessful.²⁸⁰ Subsequent approaches between 1920 and 1940 designed to inactivate or attenuate the virus by culture in chick embryos also met with limited success.⁴²⁸ The isolation of MeV in tissue culture opened the way for a more concerted approach to vaccine development using the Edmonston strain of virus.¹⁸⁴ Killed virus vaccines were developed using formalin and tween-ether for inactivation.⁷⁵⁸ Simultaneously, attenuated vaccines based on adaptation of MeV to growth in chick cells were developed and are now widely used.³⁴⁹ The attenuated live virus vaccine has dramatically decreased the incidence of measles in all countries in which it has been effectively delivered.

The live attenuated MeV vaccine induces both neutralizing antibody and cellular immune responses that are long-lasting, but the immune responses necessary for protection from infection or disease have not been completely defined. Antibody is sufficient for protection because infants are protected by maternal antibody⁹ and passive transfer of immune serum can modify or interfere with measles vaccination and partially protect children from measles after exposure.⁵⁸² The role of the cellular immune response in protection has been more difficult to study but is induced more readily than antibody in young infants and in the presence of maternal antibody.²²⁴

Inactivated Vaccines

The alum-precipitated inactivated vaccine was used in a three-dose regimen.^{97,758} Recipients developed moderate levels of neutralizing and HI antibodies and low levels of CF antibody.^{97,203,507} Studies in rhesus macaques have shown that the inactivated vaccine induces no CD8+ T-cell response and that the avidity of the MeV antibody induced does not mature.^{558,559} The vaccine was protective when exposure to measles occurred soon after immunization.^{203,219} However, antibody titers declined rapidly, and recipients again became susceptible to measles^{219,578}; when infected, they had a tendency to develop the more severe disease, atypical measles,^{486,578} discussed previously, and the vaccine was withdrawn.

Attenuated Live Virus Vaccines

The first attenuated live measles vaccine was developed by adaptation of the Edmonston strain of MeV to chick embryos and subsequently to chick embryo fibroblasts after passage in

primary renal and amnion cells to produce the Edmonston B virus.¹⁸¹ Inoculation of this virus produced no detectable viremia and no spread to the respiratory tract or disease in monkeys, but it did induce antibody and protected from subsequent challenge. This vaccine was efficacious³⁷⁴ and licensed in 1963 but produced fever and rash in a large proportion of immunized children.³⁴⁸ Reactions were reduced when MeV antibody was given at the same time as the vaccine. Further passage of the Edmonston B virus in chick embryo fibroblasts produced a more attenuated virus that was licensed in 1965.⁶⁴⁷ The Moraten strain used in the United States was licensed in 1968 and is closely related to Schwarz.⁶⁰³ Other Edmonston-derived vaccine strains (e.g., Zagreb, AIK-C) and attenuated strains developed independently (e.g., CAM, Leningard-16, Shanghai-191) are also successful vaccines. Few differences have been described among MeV vaccine strains (all genotype A) regardless of the geographic origin of the parent virus.⁶⁰³ The lyophilized vaccine is relatively stable but rapidly loses infectivity at room temperature after reconstitution.⁴⁴⁹

The recommended age of initial vaccination varies from 6 to 15 months. The probability of seroconversion and the levels of antibody induced are determined by the level of persisting MeV-specific maternal antibody and by the age of the infant.^{137,223,224,580} The recommended age of immunization is determined by a region-specific balance between the optimum age for seroconversion and probability of acquiring measles before that age.¹³⁷ In areas where measles remains prevalent, measles vaccination is routinely performed at 9 months (85% response), whereas in areas with little measles, vaccination is often at 12 to 15 months of age (95% response).¹³⁹ The standard route of administration is either subcutaneous or intramuscular, but there is substantial interest in alternative routes that would avoid the need for needles and syringes. Transcutaneous delivery has not yet been successful,²⁰⁰ and intranasal administration of reconstituted liquid vaccine elicits a local, but not a systemic, immune response.⁶⁷¹ However, respiratory delivery of aerosolized liquid vaccine has shown promise in older children,^{136,164,165,293,411} and respiratory delivery of a small-particle dry powder vaccine induces protective immunity in macaques.⁴⁰²

Host genetic differences affect the likelihood of seroconversion and level of antibody induced,^{164,573} and several specific polymorphisms that affect responses have been identified.^{123,159,160,524,525} The effect of common childhood illnesses on seroconversion is unclear,⁴⁵⁴ and any potential decrease in seroconversion must be balanced against the loss of the opportunity for vaccination and the consequent risk of the child acquiring measles. Overall, the efficacy of a single dose of measles vaccine in infancy is estimated at 77% to 84% when administered at 9 to 11 months, 92% when administered at 12 months or older, and 94% after two doses.^{224,728} Compromises must also be considered with respect to immunizing individuals with HIV infection.¹³⁸ Progressive fatal infection has been occasionally associated with measles vaccine in severely immunocompromised children and adults.¹⁹ However, in general, measles vaccine has been well tolerated in HIV-seropositive children,⁶⁴⁸ although the seroconversion rate is lower, antibody is of lower avidity, and titers wane more quickly than in HIV-uninfected children.^{213,477,488} Because of the potential severity of measles in these individuals, the vaccine is recommended for routine administration to infants without respect to HIV

serostatus in most countries, unless the CD4+ T-cell count is known to be low.

The dose of MeV routinely used for immunization is between 10^3 and 10^4 plaque-forming units. Ten- to 100-fold higher doses improved seroconversion in younger infants, but subsequent follow-up of children receiving high-titered vaccines in countries with high childhood mortality showed an increased mortality in girls over the subsequent 2 to 3 years.^{296,363} Mortality was not due to measles, but rather to a relative increase in the deaths due to other infections.² The pathogenesis of delayed increased mortality after high-titered vaccine is not understood but occurred primarily in those who developed a rash after vaccination and may be related to long-term suppression of immune responses similar to that induced by measles.⁶⁵¹

The immune response to the live attenuated vaccine is similar to that induced by natural disease. However, the duration of vaccine-induced immunity appears to be more variable. In general, levels of antibody are lower after vaccination than after recovery from natural disease, and MeV-specific antibody and CD4+ T cells decay with time.^{122,495} Secondary vaccine failure rates have been estimated at approximately 5% 10 to 15 years after immunization but are probably lower when vaccination is given after 12 months.^{17,433} A second dose of vaccine is necessary to immunize persons who did not respond to the first dose.^{114,138,228} The second dose can be delivered as a part of a routine vaccination program or in national or regional supplementary immunization campaigns. The two-dose strategy has been credited with elimination of indigenous measles in a number of countries.¹³⁸

Experimental Vaccines

Development of new vaccines has been hampered by an incomplete understanding of protective immunity and of the priming for enhanced disease by the inactivated vaccine. Nevertheless, a number of experimental vaccines have been developed. The primary motivations for development of a new vaccine are to increase thermostability, to provide a vaccine that can be given to young infants, and to avoid the hazards associated with the use of needles and syringes. Vaccination with the H, F, and/or N protein expressed in bacterial, poxvirus, adenovirus, or bacille Calmette-Guérin (BCG) vectors or as DNA, peptides, or proteins can induce cellular and humoral immunity in mice and cotton rats.^{116,199,407,532,678,684,762} Monkeys are the most relevant model system, and studies have shown different degrees of protection after vaccination with H, F, and/or N expressed with BCG, alphavirus replicon particles, vaccinia virus, immune-stimulating complexes, and variously formulated DNAs.^{529,533,557,566,685,686,733,805,806}

Prospects for Eradication

Theoretically, measles is an ideal virus for eradication through vaccination: there is only one serotype; most cases are clinically identifiable; there is no animal reservoir; and a vaccine is available.⁴⁷³ However, measles remains a leading cause of vaccine-preventable childhood mortality.¹¹⁵ In 1979, eradication was identified as a goal for the United States, but it was 20 years before endemic transmission was interrupted.¹¹² In 2010, the World Health Assembly endorsed 2015 targets of greater than 90% national coverage with one dose of vaccine, reduction of measles incidence to less than 5 cases per million, and mortality reduction of greater than 95% compared to

2000 estimates. The highly communicable nature of the virus requires continued maintenance of high vaccine coverage to prevent outbreaks, with 95% to 98% seropositivity needed for herd immunity. The role of asymptomatic infection of partially immune individuals in maintaining transmission is unclear. Global programs, such as the Expanded Program for Immunization and the Measles Initiative, have increased vaccine coverage worldwide and have resulted in significant decreases in measles and measles mortality.^{139,474} However, delivery remains difficult in many areas due to civil strife, the need to maintain a cold chain, decreasing donor support, and religious or philosophical resistance to vaccination.^{113,474} Eradication remains a worthy but difficult goal.⁶⁸⁹

Perspective and Geographic Considerations

suburb where the outbreak occurred. A second person died from HeV infection 13 months after the Brisbane outbreak, a farmer from Mackay, nearly 1000 km north of Brisbane. Unlike the first case, however, the man succumbed to encephalitis caused by HeV infection.¹⁰⁷ A forensic investigation found that the farmer had suffered a mild meningitic illness 14 months earlier after assisting at the necropsy of two horses that had died of severe respiratory distress—later found to have been caused by HeV¹²⁵—and that he became infected at that time. After initial serologic evidence suggested that fruit bats (flying foxes) of the genus *Pteropus* in the suborder *Megachiroptera* were the reservoir hosts,¹⁶⁵ HeV was isolated from two species of flying fox. In total, there have been 14 recognized occurrences of HeV in Australia between 1994–2010, with at least one occurrence per year since 2006.^{5,10} Every occurrence of HeV has involved horses as the initial infected host, causing lethal respiratory disease and encephalitis, along with a total of seven human cases arising from exposure to infected horses, among which four have been fatal and the most recent in 2009.^{6,10,115}

Nipah virus (NiV), the second known member of the genus *Henipavirus*, emerged as the cause of an outbreak of disease in pigs and humans in Peninsular Malaysia in 1998 through 1999. The epidemic started in Perak State as clusters of cases of encephalitis among pig farmers. It was initially believed to be caused by Japanese encephalitis virus; however, various features of the outbreak, including a high proportion of cases in direct contact with pigs and illness and deaths in pigs, differed from those expected with Japanese encephalitis.³⁰ Indeed, respiratory illness and encephalitis in pigs preceded human cases in the same district.⁹⁷ The epidemic spread south to the intensive pig-farming areas of Negeri Sembilan in December 1998 and subsequently peaked between February and April 1999. More than 1 million pigs were destroyed to halt the spread of the epidemic, and by late May, 265 human cases of acute encephalitis with 105 deaths were recorded.^{29,30} A cluster of 11 cases with 1 death occurred among abattoir workers in Singapore.¹¹⁴ In early March 1999, a virus was isolated from the cerebrospinal fluid (CSF) of a patient with encephalitis and identified as the etiologic agent.^{29,30} Named *Nipah virus* after the village from which the patient had come, it was shown to be closely related to HeV. NiV was subsequently isolated from the urine of Malaysian flying foxes.³³ The virus re-emerged in Bangladesh in 2001,⁶⁸ and outbreaks of NiV-related encephalitis have occurred in people from that country almost every year since, along with two reports of NiV encephalitis in India^{23,60} and the most recent occurrence in early 2011 in Bangladesh.⁷ The human case fatality rate of these occurrences of NiV has approached 75%.^{68,85}

HISTORY

Hendra virus (HeV), the first known member of the genus *Henipavirus* in the family *Paramyxoviridae*, came to light in September 1994 as the causative agent of a sudden outbreak of acute respiratory disease in thoroughbred horses at a stable in Brisbane, Australia. A total of 21 horses and 2 humans (a horse trainer and a stable hand) became infected. The horse trainer and 14 horses died, and 7 horses with mild or subclinical infection were killed.¹³⁰ A virus was isolated, called *equine morbillivirus* but later named *Hendra virus* after the Brisbane

INFECTIOUS AGENT

Classification

When HeV was first isolated in 1994, partial sequencing of the matrix gene (M) revealed that it most closely resembled members of the genus *Morbillivirus* in the subfamily *Paramyxovirinae*.¹⁰⁴ Subsequent characterization of the full-length genome, however, revealed that many of the genetic features of HeV were unique among paramyxoviruses and that the virus did not fit within any of the three genera existing at that time, *Morbillivirus*, *Respirovirus*, and *Rubulavirus*.^{147,148} When NiV was isolated in 1999, it was initially described as Hendra-like on the basis of its strong reactivity with anti-HeV antibodies. Later it was shown that sera raised against HeV were able to neutralize NiV and vice versa, and that both viruses shared a high degree of similarity in genome organization and protein size and sequence.^{29,58,59,146} In 2002, the genus *Henipavirus* was created to accommodate these novel paramyxoviruses, and HeV was designated the type species.⁷⁵ Currently, the genus *Henipavirus* contains two virus species and several strains isolated from humans, bats, horses, and pigs over a wide geographic area and spanning a period of 15 years (Table 37.1). The susceptibility

of humans, the virulence of the viruses, and absence of therapeutics and vaccines led to classification of HeV and NiV as biosafety level 4 (BSL4) pathogens.

Propagation in Cell Culture and Cytopathic Effect

The ultrastructural characteristics of henipavirus-infected cells resemble those found in cells infected by other members of the *Paramyxovirinae*. Shared features include generation of large syncytia and the presence of viral nucleocapsids in cytoplasmic inclusion bodies and underlying electron-dense areas of the plasma membrane.^{49,69} In Vero cells, NiV-induced syncytia are significantly larger than those generated by HeV and nuclei and nucleocapsids are frequently located at the cell periphery, compared with HeV-induced syncytia, where they tend to be more centrally located or distributed randomly throughout the cytoplasm (Fig. 37.1). Henipavirus-infected cells also contain structures that are not seen with other paramyxoviruses—specifically a network of membrane-like reticular structures in the cytoplasm and long tubules that appear to be continuous with the plasma membrane in NiV-infected cells. Tubules can also be observed in NiV virions (Fig. 37.2A). *In situ* hybridization suggests that

TABLE 37.1 Summary of Henipaviruses Isolated from Different Species and Geographic Locations

FIGURE 37.1. Syncytia induced in vero cells 24 hours after infection by Hendra virus (HeV) (A) and Nipah virus (NiV) (B). Methanol-fixed infected cells were labeled with rabbit monospecific antiserum to the HeV P protein and fluorescein-conjugated goat antirabbit immunoglobulin G. P protein is detected in extensive perinuclear ribonucleoprotein complexes (*small arrow*) and in discrete regularly shaped arrays (*large arrow*) distributed throughout the cytoplasm and believed to be sites of virus egress from the cell. Nuclei are indicated by *chevrons*.

these reticular structures contain viral RNA and may play a role in viral transcription.⁴⁹

Virus Morphology

Henipavirus particles are pleomorphic, varying from spherical to filamentous and ranging in size from 40 to 1,900 nm.^{49,69,104} Nucleocapsids have a diameter of 18 to 19 nm with an average pitch of 5 nm. When examined by electron microscopy (EM), HeV has a unique double-fringed appearance, caused by the presence of surface projections 15 ± 1 nm and 8 ± 1 nm in length (see Fig. 37.2B). Approximately 95% of virions contain the double fringe, and the remaining 5% display a uni-

form fringe length of 15 ± 1 nm. Unlike HeV, NiV possesses a single layer of surface projections with an average length of 17 ± 1 nm, and NiV particles released into the culture medium are difficult to image because they are routinely penetrated by negative stains. This suggests that the viruses may differ in the physical nature of their envelope.⁶⁹

Genome Length and Organization

In the subfamily *Paramyxovirinae*, the genome length of all characterized viruses is divisible by six, an observation caused by the requirement of each N protein in the viral ribonucleoprotein to bind 6 nucleotide (nt) residues.⁷⁶ This is also true

FIGURE 37.2. A: Electron micrograph of Nipah virus (NiV)-infected Vero cells showing tubule-like structures, both in the cytoplasm and in a maturing virus particle (*arrows*). B: Electron micrograph of negatively stained Hendra virus (HeV) displaying the double fringe at the virus envelope (*small arrow*) and the herringbone nucleocapsids (*large arrow*). FIGURE 37.3. Genome size and organization of Hendra virus compared with type species of each of the other four classified genera in the subfamily *Paramyxovirinae*. Genome lengths (in nucleotides) are given in brackets after each virus.

for HeV and NiV despite their much larger genome sizes.¹⁴⁶ The genomes of the Malaysian and Bangladesh strains of NiV differ by 6 nt because of a 6-nt increase in the 3' untranslated region of the *F* gene.⁵⁷ A minigenome replicon study confirms that NiV complies with the rule of six.⁵⁵ When the complete genome sequence of HeV was determined, its length (18,234 nt) was more than 2,700 nt, or 15% longer than the genomes of all other paramyxoviruses known at that time.¹⁴⁸ The size of the NiV genome at 18,246 nt to 18,252 nt is slightly larger than that of HeV.^{57–59} The extra length of the henipavirus genome is in the form of unique, long untranslated sequences at the 3' end of five of the six genes. A comparison of genome length and untranslated regions of representative members of the *Paramyxovirinae* is shown in Figure 37.3.

The genome organization of henipaviruses resembles that in the genera *Respirovirus* and *Morbillivirus*. The first 12 nt of the 3' and 5' genomic terminal sequences of paramyxoviruses are highly conserved and complementary, containing promoter elements for replication and transcription.⁷⁶ The first 3 nt of the henipavirus genome termini are 5'-ACC-3'—a sequence that is absolutely conserved in members of the subfamily *Paramyxovirinae* but different from that found in the *Pneumovirinae*.

Genetic Diversity

Partial genome sequencing revealed that HeV isolated from equine and human sources during the outbreak in Brisbane appears identical and differs little from HeV isolated from flying foxes 2 years later.^{56,104} Sequencing of five additional horse isolates from five different locations from the 2006 to 2008 HeV occurrences has demonstrated a very high genetic

similarity.⁹⁰ Similar observations were made in Malaysia, where it was demonstrated that NiV isolated from pigs at the height of the outbreak and at its geographic focus were essentially identical to human isolates made at that time and isolates obtained from flying foxes several years later.^{2,24,33,58,59}

In Bangladesh, four human isolates obtained in 2004 demonstrate significant genetic heterogeneity and suggest multiple spillovers of NiV from flying foxes into the human population.⁵⁷ The NiV sequence detected from lung tissue of human patients in India was more related to NiV from Bangladesh than NiV from Malaysia.^{9,23} On the other hand, NiV isolated from the flying fox *Pteropus lylei* in Cambodia¹²⁰ represents an evolutionary lineage that is separated from the Malaysia or Bangladesh/India cluster (Fig. 37.4). Partial *N* gene sequences detected in *Pteropus lylei* in Thailand indicate the circulation of at least two lineages of NiV—one related to the Bangladesh NiV and the other more related to the Malaysian NiV.¹⁴⁴

The presence of henipavirus-reactive (but not neutralizing) antibodies in bats from other regions of the world (see Epidemiology section) predicts that a much greater genetic diversity of henipaviruses exists in different bat populations. This also suggests the existence of henipaviruses with different transmissibility and pathogenicity in nonbat hosts.

Virus Proteins and Their Properties

Analysis of purified viruses by polyacrylamide gel electrophoresis reveals L, P, G, F₀, N, F₁, and F₂ proteins,^{146,147} where F₀ is the uncleaved and F₁ and F₂ the cleaved products of the *F* gene. Interestingly, F₀ is more readily detected in HeV compared with other paramyxoviruses, including NiV.^{93,146} Overall, the proteins

FIGURE 37.4. Phylogenetic relationship between the N protein sequences of henipavirus isolates from different geographic locations. The virus nomenclature abbreviation follows the following format: virus/country origin/host/year/isolate name. For example, NiV/KH/BA/2004/KHM represents a Nipah virus isolated from bats in Cambodia in 2004 with KHM as its isolate name.

of henipaviruses are typical of those of the subfamily *Paramyxovirinae*, with the exception of the P protein, which is significantly larger than cognate proteins in the subfamily.¹⁴⁷ The P protein is translated from messenger RNA (mRNA) that is co-linear with genomic RNA. The P gene also encodes V and W proteins, produced from mRNA in which one and two nontemplated G residues, respectively, are inserted at the RNA editing site during transcription. The P, V, and W proteins, therefore, are identical for the first 405 amino acid residues. A C protein is encoded by the 5' end of the gene in an overlapping reading frame and is produced by an internal translational initiation mechanism, which is common to other members of *Paramyxovirinae*, except for rubulaviruses.⁷⁶ The P, V, and the C proteins predicted from the coding regions in the P gene are present in HeV-infected cells.¹⁴⁶ The functional expression of W in NiV-infected cells has recently been demonstrated.⁸⁴

Paramyxovirus N, P, and L proteins are necessary and sufficient for replication of viral RNA both *in vitro* and *in vivo*,⁷⁶ and this has been confirmed for henipaviruses by reverse genetics. Using a minigenome replicon containing leader and trailer sequences of the NiV genome with its entire coding region replaced with a reporter gene, it was shown that efficient genome replication was achieved only when all three proteins were expressed in the same cell.⁵⁵ NiV N, P, and L proteins were also able to rescue a minigenome constructed from the leader and trailer sequences of the HeV genome, further demonstrating the close genetic relationship between the viruses.

The L protein of nonsegmented, negative-stranded RNA (NNR) viruses in the order *Mononegavirales* contains a highly conserved GDNQ motif, believed to be important for polymerase activity.¹¹⁶ Henipaviruses were the first NNR viruses in which GDNQ was replaced by GDNE. It was speculated that this motif might be unique to paramyxoviruses with relatively large genomes^{146,148}; however, the GDNE motif has since been found in the L protein of Mossman virus that has a genome length of 16,650 nt.⁹⁶

The cell attachment proteins of the *Paramyxovirinae* display hemagglutination (H) and neuraminidase (N) activities in a predominantly genus-specific manner. Viruses in the genera *Respirovirus*, *Avulavirus*, and *Rubulavirus* possess both activities,⁷⁶ whereas viruses in the genus *Morbillivirus* do not behave uniformly and only some possess hemagglutination activity.⁷⁷ In contrast, henipavirus attachment proteins have neither of these activities^{146,166}; rather, they utilize the host cell expressed ephrin-B2 and ephrin-B3 molecules as attachment and entry receptors.^{11,13,105,106} Recent solution structures of the henipavirus G glycoprotein alone and in complex with the ephrin-B2 and ephrin-B3 receptors have revealed the details of the virus–host cell binding process, distinguishing it from other paramyxovirus receptor strategies.^{20,21,163}

Proteolytic processing of paramyxovirus F proteins is essential for the generation of a fusogenic form of the protein. For most paramyxoviruses that generate systemic infections, cleavage is catalyzed by the cellular protease furin at a multibasic cleavage site.⁷⁶ Surprisingly, henipavirus F proteins are cleaved without the involvement of furin and, although cleavage occurs at a single basic residue—lysine for HeV and arginine for NiV⁹⁸—activation of the NiV F protein does not require a basic amino acid at the cleavage site.⁹³ It has been shown that the lysosomal cysteine protease cathepsin L is responsible for the cleavage of the HeV F protein.¹⁰⁸ The cytoplasmic tails of henipavirus F proteins contain the endocytosis consensus motif YXX ϕ .^{92,143} Endocytosis is required for cleavage activation of the F protein,^{35,92} consistent with identification of cathepsin L as the enzyme responsible for cleavage.

Host Range

For most paramyxoviruses, host range is limited and interspecies transmission is rare. In contrast, henipaviruses display a broad species tropism. In addition to at least three flying fox species, two nonpteropid fruit bat species, and an insectivorous species, NiV has naturally infected pigs, humans, dogs,

horses, and cats,^{29,63,97,120,164} whereas HeV infects four Australian flying fox species and has naturally infected humans and horses.^{42,104} Confirmation of the wide host range of henipaviruses and the identical cell tropism of HeV and NiV were obtained early using an *in vitro* cell fusion system that relies on vaccinia virus-mediated cell surface expression of G and F glycoproteins.^{17,18,136} Guinea pigs, hamsters, ferrets, squirrel monkeys, and African green monkeys are also susceptible to experimental NiV infection.^{19,46,88,94,157} Laboratory studies have added cats, guinea pigs, hamsters, and African green monkeys to the list of HeV-susceptible species,^{53,121,151,156} along with ferrets (J. Pallister and L.-F. Wang, unpublished results).

PATHOGENESIS AND PATHOLOGY

Cell and Tissue Tropism

The primary site of NiV replication and the dynamics of virus spread in humans are unknown. However, the distribution and time of appearance of lesions throughout the vasculature and in the brain and lung in NiV encephalitis suggest that secondary infection probably arises via hematogenous spread of the virus, with secondary replication occurring in vascular endothelium.¹⁵⁹ Inflammation of blood vessels occurs in most organs but is particularly prominent in the brain, lung, heart, and kidney.^{30,159,160} Vasculitis is limited to small arteries, arterioles, and capillaries where NiV antigen is found in both endothelial cells and the smooth muscle of the tunica media. The pattern and time of appearance of vasculitis and viral antigen distribution are consistent with endothelial cell infection occurring before infection of the smooth muscle. Syncytial endothelial cells are present in blood vessels of various organs and represent a pathognomonic but insensitive feature of henipavirus infections found in only 25% of human NiV infections.¹⁵⁹ Syncytial endothelial cells were also observed in the single human case of encephalitis caused by HeV.¹⁰⁷ NiV antigen is also found in neurons and, less frequently, in bronchiolar and renal epithelial cells. The 5-day interval between maximal vasculitis in the brain and parenchymal infection in acute NiV encephalitis suggests that primary virus replication occurs in endothelial cells, with infection of neurons occurring as a result of vascular damage. The presence of inclusion bodies and viral antigen in neurons suggests that neurologic impairment in encephalitis may be caused by both the effects of ischemia and infarction and viral infection of neurons.^{30,114,159} Human HeV encephalitis has been described as widespread cortical, subcortical, and deep white matter involvement in two cases in 2008¹¹⁵ and similar to those described in a previous HeV encephalitis case^{82,107} and NiV encephalitis cases.^{82,127}

Although NiV antigen is found less frequently in bronchiolar and renal epithelial cells compared with vascular and neuronal locations, replication in epithelial locations may play a role in virus dissemination, because NiV is found in urine and in tracheal and nasopharyngeal secretions of infected patients in the early phase of their illness.^{31,48} Despite this, human-to-human transmission in Malaysia was extremely rare.¹⁰⁰

The identification of ephrin-B2 and ephrin-B3 as functional receptors for henipaviruses in cultured cells provides an explanation for the observed distribution of viral antigen in arterial endothelial cells, smooth muscle, neurons, and some epithelial cells.^{11,13,105,106} Ephrin-B2 is found in arteries, arterioles,

capillaries in multiple organs, and tissues including arterial smooth muscle and human bronchiolar epithelial cells¹³⁵ but is absent from venous components of the vasculature.⁴⁵ Ephrin-B3 is found predominantly in the nervous system as well as the vasculature.¹¹³ The ephrins engage Eph receptors and mediate bidirectional cell–cell signaling events and are modulators of cell remodeling events, especially within the nervous and vascular systems.¹¹³

Immune Response

In patients with encephalitis, anti-NiV antibodies were observed more frequently in the serum than the CSF. Immunoglobulin M (IgM) antibodies occurred more frequently than immunoglobulin G (IgG) antibodies in both locations.^{30,114,159} The appearance of specific IgM antibodies in serum preceded their appearance in the CSF, a sequence consistent with viremia preceding central nervous system (CNS) infection. Anti-NiV antibodies were present in most patients with clinical NiV encephalitis; however, no difference was observed in clinical features, laboratory results, or mortality between seropositive and seronegative patients.^{27,48} Seroconversion of IgG against HeV was seen in two human cases of HeV infection, one fatal, in 2008,¹¹⁵ following an influenza-like illness and before progressing to encephalitis.

Inhibition of the Interferon Response

In henipaviruses, as in other paramyxoviruses,⁶⁶ anti-interferon (IFN) activities are encoded by the *P* gene and *in vitro* studies indicate that *P* gene products inhibit both IFN induction and signaling.³⁷ In IFN induction, viral double-stranded RNA (dsRNA) is detected by intracellular RNA helicase enzymes^{3,79} and by toll-like receptor 3 (TLR-3).¹² Both of these dsRNA signaling pathways lead to activation of the pre-existing transcription factors interferon regulatory factor 3 (IRF-3) and nuclear factor kappa B (NF- κ B),⁵⁰ and the synthesis of IFN- α and a subset of IFN- β proteins.⁸⁹ HeV inhibits dsRNA signaling by using a strategy adopted by other paramyxoviruses in which the V protein binds to the intracellular RNA helicase sensor and prevents downstream signaling³ but does not abrogate dsRNA signaling through TLR-3.¹³² In an additional strategy unique to henipaviruses, the W protein, by virtue of a nuclear localization signal located in the unique carboxy terminal, inhibits dsRNA signaling in the nucleus by targeting a process that is part of both helicase-dependent and TLR-3-dependent signaling pathways.¹³²

In the IFN signaling pathway, IFN binds to cell surface receptors in a paracrine manner and initiates a signaling sequence that leads to activation of members of a family of proteins called *signal transducers and activators of transcription* (STAT).^{1,50} Henipaviruses inhibit IFN signaling by sequestering STAT proteins in high molecular weight complexes.^{123,124} The anti-IFN signaling activity is a property of the V protein, as has been observed for other paramyxoviruses, but also of the W and P proteins.^{123,124,133} The P, V, and W proteins of henipaviruses have an N-terminal extension of 100 to 200 amino acids compared with cognate proteins in the subfamily,^{59,147} and the STAT binding domain of NiV V maps to this region.¹²² The V and P proteins bind STAT in the cytoplasm, whereas the W protein, with its nuclear localization signal, co-localizes with STAT in the nucleus.^{132,133} The W protein is the most and P protein the least efficient IFN antagonist.¹¹² The NiV

C protein also displays a modest inhibition of IFN signaling, although the mechanism and target are unknown.¹¹²

It should be noted that most, if not all, studies described previously were carried out *in vitro* using single-gene transfection expression systems. A recent study conducted using live virus infection indicated that IFN signaling remains functional during henipavirus infection of human cell lines, whereas IFN production was inhibited.¹⁴²

Infections of Animals

Only limited data are available on the minimal lethal and infectious doses of henipaviruses. In golden hamsters (*Mesocricetus auratus*), the NiV lethal dose 50% (LD₅₀) following intraperitoneal and intranasal administration was 270 and 47,000 plaque-forming units (pfu), respectively,¹⁵⁷ and was calculated to be 12 pfu for HeV by intraperitoneal injection.⁵³ The NiV minimal infectious dose in hamsters is 100 pfu if the intraperitoneal route is used and 10³ pfu if the virus is administered intranasally. Guinea pigs and pigs are also more resistant to infection by HeV and NiV, respectively, when the viruses are administered by the oronasal route compared with the subcutaneous route.^{95,154} In contrast, both HeV and NiV appear to be equally infectious for cats following either parenteral (5,000 tissue culture infectious dose 50% [TCID₅₀] virus) or oronasal (50,000 TCID₅₀ virus) administration.^{64,91,95,101,151}

Experimental infection of horses with HeV by parenteral or oronasal routes is almost uniformly fatal, with death or euthanasia usually occurring 5 to 10 days after infection. Several horses in the original outbreak in Hendra survived infection, however, some asymptotically.^{103,104,156} In horses, HeV displays a predominantly respiratory tropism, and infection is characterized by pulmonary edema and congestion.^{64,104,156} In field cases, the airways are often filled with a blood-tinged frothy exudate. Neurologic signs do exist, but they have been observed infrequently in terminally ill horses and in horses that recovered from respiratory infection.^{125,156} Infection is associated with virus replication and with the appearance of viral antigen in endothelial cells in a wide variety of organs, including lungs, lymph nodes, kidneys, spleen, bladder, and meninges. The subsequent degeneration of small blood vessels is accompanied by the appearance of syncytial endothelial cells.⁶³ Virus can be recovered from several internal organs, including lung, and from saliva and urine.^{64,156}

In contrast, NiV infection of pigs is frequently asymptomatic, particularly following natural infection and after experimental administration of the virus by the ocular and oronasal route.^{95,97,150} When symptoms are present, they vary according to the age of the pig, with older animals presenting primarily with a neurologic syndrome, whereas a respiratory syndrome predominates in young animals. The virus manifests respiratory and neurologic tropisms in both asymptomatic and clinical infections.^{95,149} Neurologic signs include trembling and neurologic twitches, muscle spasms, and uncoordinated gait.⁹⁷ After experimental NiV infection of young pigs by the ocular and oronasal routes, virus replication occurs in the oropharynx and spreads sequentially to the upper respiratory tract and submandibular lymph nodes, the lower respiratory tract, and additional lymphoid tissues.¹⁴⁹ Here, viral antigen is widespread and syncytia are common in clinically affected animals as a result of replication in the endothelial and smooth muscle cells of medium to large veins as well as in the

arteries of the central nervous, lymphoid, and respiratory systems.^{63,95,149} NiV invades the CNS via the cranial nerves and by crossing the blood–brain barrier.¹⁴⁹ Virus is recovered from a range of tissues, including tonsil, nasal, and throat swabs and lung, but is recovered infrequently from urine.^{34,95,149} Experimental HeV infection of pigs (Landrace and Gottingen mini-pig breeds) via oronasal or nasal inoculations has shown both to be susceptible to infection,⁸⁰ with virus detected mainly in tissues from respiratory and lymphoid systems, and could be isolated from nasal, oral, and rectal swabs, indicating the possible routes for virus shedding.

Laboratory Animal Models

In hamsters, the pathologic features following NiV infection resemble those found in humans.¹⁵⁷ Hamsters die 5 to 9 days after intraperitoneal administration of 100 to 10,000 infectious particles and 24 hours after the appearance of tremors and limb paralysis. In contrast, hamsters inoculated intranasally with doses as high as 10³ to 10⁶ infectious particles die between 9 and 15 days later, displaying progressive deterioration with limb paralysis, lethargy, limb twitching, and breathing difficulties. Vascular pathology is observed in a range of organs, including brain, lung, liver, kidney, and heart, and viral antigen and genome are found in endothelial cells. The brain is the most severely affected organ, with the vascular and parenchyma lesions consistent with CNS-mediated clinical signs.¹⁵⁹ HeV infection of hamsters also resembled the pathology seen in acute human cases, including both respiratory and brain pathology.⁵³ HeV-induced pathology in the hamster was similar to that of NiV¹⁵⁷ and consisted of endothelial infection and vasculitis with thrombosis and microinfarction, with evidence of direct parenchymal cell infection, notably in the CNS.

In cats, the first clinical signs, which are observed on days 4 to 8 after parenteral or oronasal administration of HeV and NiV, include depression, fever, and an increased rate of respiration.^{65,101,151,152} Most infected animals die 1 day after the appearance of respiratory distress. The disease caused by HeV and NiV in cats closely resembles that seen in HeV-infected horses, with copious frothy sanguineous fluid in the bronchi and hemorrhage or congestion of the tracheal epithelium.⁶⁴ Vaculitis affects both arteries and arterioles, and syncytial cells are observed in endothelia, predominantly in the lungs but also in gastrointestinal, spleen, and lymphoid organs. A major difference between NiV and HeV infection of cats is the extensive degree to which NiV, but not HeV, infects the respiratory epithelium.⁹⁵ Henipaviruses are found in the urine and bladder of experimentally infected cats, and NiV can transplacentally infect and replicate in fetal tissues with high levels of recoverable virus from the placenta and uterine fluid.¹⁰²

In guinea pigs, the clinical response to henipavirus infection is frequently mild and often variable, ranging from inapparent to sudden death, with only a proportion of animals displaying signs such as transient weight loss, depression, ataxia, lethargy, and twitching.^{154,157} The vascular tropism of HeV in guinea pigs is evident in many organs.⁶⁵ Death appears to result from vascular disease in a variety of organs.⁶⁵ Only a proportion of infected animals develop encephalitis with virus observed in blood vessels and neurons.¹⁵⁴

A ferret model of henipavirus infection and pathogenesis has also been developed.^{19,110} The ferret exhibits both severe

respiratory and neurologic disease as well as generalized vasculitis following an oronasal challenge with NiV with doses as low as 500 TCID₅₀ within 6 to 10 days postinfection. Clinical signs in affected ferrets included various combinations of severe depression, cough, serous nasal discharge, dyspnea, subcutaneous edema of the head, cutaneous ecchymoses, and obtundation with tremor and hind limb paresis depending on the challenge dose. Clinical disease in the ferret included vascular fibrinoid necrosis in multiple organs, necrotizing alveolitis, and syncytia of endothelium and alveolar epithelium. Histopathologic lesions included severe focal necrotizing alveolitis, vasculitis, degeneration of glomerular tufts, and focal necrosis in a wide range of other tissues. High levels of viral antigen were noted in blood vessel walls, and syncytial cells were frequently present. Viral antigen was present in neurons, and infectious NiV was isolated from multiple organs including the brain. Overall, NiV-mediated disease observed in the ferret model manifested with all the hallmarks seen among NiV-infected humans, and essentially identical results have been observed with HeV infection of ferrets (J. Pallister and L.-F. Wang, unpublished results).

A nonhuman primate model of henipavirus infection has been developed using the African green monkey,^{46,121} which yields a uniformly lethal disease with doses as low as approximately 2×10^4 pfu (NiV) or 4×10^5 TCID₅₀ of HeV. Monkeys, following intratracheal inoculation with either NiV or HeV, reveal a rapid spread of the virus (3–4 days postinfection) to numerous organ systems. NiV-infected monkeys developed a severe acute respiratory distress syndrome (ARDS)-like disease, associated with copious amounts of sanguineous fluid and froth. The lungs are enlarged with multifocal areas of congestion and hemorrhage, and immunohistochemical and histopathologic examination revealed significant amounts of polymerized fibrin and NiV antigen.⁴⁶ Endothelial syncytial cells were prominent in most of the tissues, and vasculitis was widespread. NiV antigen was present in endothelial and arterial smooth muscle cells in most examined tissues. Respiratory disease development could be seen within 7 days postinfection with either NiV or HeV following intratracheal inoculation by radiologic examination^{46,121} progressing to severe congestion and infiltration in the lung fields.

NiV and HeV could be found in virtually every organ system sampled at the time of death in the African green monkey. Immunohistochemical and histopathologic analysis revealed the presence of NiV antigen, predominantly in endothelial cells and smooth muscle cells, along with associated pathology. Most animals showed evidence of henipavirus-induced neurologic disease,^{46,121} with severe congestion and evidence of meningeal hemorrhaging and edema. NiV and HeV antigen was detected in endothelial cells in brain, with infection of neurons often widespread in the brain stem.^{46,121} NiV infection of squirrel monkeys has also been examined.⁸⁸ Although some animals demonstrated limited similarities to NiV pathogenesis in humans, only 50% of challenged animals exhibited any clinical signs, with most remaining well even following intranasal or intravenous delivery of doses as high as 10^7 pfu of NiV.

Unlike the cat, guinea pig, hamster, and squirrel monkey models of NiV or HeV infection, severe respiratory pathology, neurologic disease, and generalized vasculitis all occur in henipavirus-infected African green monkeys, providing an accurate reflection of what is observed in henipavirus-infected humans.

EPIDEMIOLOGY

Age

The age of patients with encephalitis in the Malaysian outbreak ranged from 9 to 76 years, with almost 50% of cases occurring in those 40 to 44 years.^{27,28,48,111,159} The male-to-female ratio was approximately 3:1, and more than 80% of the patients were Chinese, with statistics reflecting the increased risk to those working with infected pigs.^{48,111} In Bangladesh, the age of patients ranged from 4 to 60 years, and males constituted 47% and 67% of the cases in the 2001 and 2003 outbreaks, respectively.^{43,68} The recent outbreak in early 2011 in Bangladesh claimed at least 35 lives, including many children and infants, with ages ranging from 2 to 56 years.⁸

Morbidity and Mortality

In Malaysia, between September 1998 and June 1999, 256 patients who developed acute NiV encephalitis were admitted to Malaysian hospitals and 105 died, a mortality rate of approximately 40%.^{30,111} The rate of subclinical infection in households and farms where cases of NiV encephalitis occurred was calculated to be 8% and 11%, respectively.^{111,139} In Singapore, where 11 patients were confirmed to have acute NiV encephalitis, a further 2 asymptomatic abattoir workers were serologically positive, representing a rate of subclinical infection of 15%.²⁵ Subsequently, 89 individuals were identified on the basis of positive serology as having experienced either an asymptomatic or mildly symptomatic NiV infection.¹³⁸ This increases the number of people infected with NiV to 345 and decreases the mortality rate to approximately 30%.¹⁶⁰ In Bangladesh, 98 of 135 patients died in eight outbreaks from 2001 to 2008, giving a combined case fatality rate of 73%.^{43,62,85} There have only been seven known human cases of HeV infection in Australia in the past 16 years, four of which have been fatal (three acute and one case of relapsed encephalitis).^{6,104,107,115}

Origin and Spread of Epidemics

Fruit bats (flying foxes) in the genus *Pteropus*, family *Pteropodidae*, suborder *Megachiroptera* are main reservoir hosts of HeV and NiV.^{33,56,164,165} In Australia, HeV has been shown to occur in four flying fox species, with the crude seroprevalence of 47%, indicating an endemic pattern of infection throughout Australia.⁴² Serologic tests show that NiV is widely dispersed in pteropid bats in Malaysia, especially the Island flying fox (*Pteropus hypomelanus*) and the Malayan flying fox (*Pteropus vampyrus*).¹⁶⁴ NiV was first isolated from the urine of Island flying foxes and from the saliva on partially eaten fruit³³ and has since been isolated from Lyle's flying foxes (*Pteropus lylei*) in Cambodia.¹²⁰ The Indian flying fox (*Pteropus giganteus*) is the only pteropid species throughout Bangladesh and the Indian subcontinent with a high seroprevalence of henipavirus-specific antibody.^{39,68,86,87} Additional serologic and limited nucleic acid evidence has suggested that related henipaviruses are circulating in other regions, including Thailand, Indonesia, China, Madagascar, and West Africa.^{36,61,70,81,131,145}

Neither HeV nor NiV appear to cause clinical disease in flying foxes infected naturally,^{42,43,119,164} and experimental infection with doses of HeV, consistently shown to be lethal in horses, generates only sporadic vasculitis in the lung, spleen, meninges, kidney, and gastrointestinal tract and only in a proportion of infected bats.¹⁵⁶ Viral antigen is detected in the tunica media

rather than endothelial cells, a fact that may spare the flying fox from the clinical effects associated with vasculitis.³⁷ In infected pregnant flying foxes, antigen was observed in similar locations and in the placenta.¹⁵⁵ The mode of transmission between flying foxes is unknown. Transplacental transmission has also been observed experimentally without apparent harm to the fetus.¹⁵⁵ Experimental infection of flying foxes with NiV produced a subclinical infection with a transient presence of virus within selected viscera along with periodic viral excretion in bat urine and seroconversion with neutralizing antibody present.⁹⁴

The spillover and epidemic hosts of HeV and NiV were horses in Australia and pigs in Malaysia. All human infections with HeV in Australia and NiV in Malaysia have only occurred through transmission from these domestic animal hosts.^{30,111} No evidence exists of direct transmission from pteropid bats to humans in Australia or Malaysia, despite many opportunities in Australia for transmission to bat carers.^{127,129} In contrast, flying foxes apparently play a direct role in the transmission of NiV to humans in the many recent outbreaks of disease in Bangladesh, where epidemiologic evidence in support of a role for pigs was lacking.^{43,68} Three pathways of NiV transmission from bats to people have been identified based on epidemiologic investigations in Bangladesh.⁸⁵ Consumption of fresh date palm sap appears to be the predominant risk factor, and infrared camera studies have confirmed that *P. giganteus* bats frequently visit date palm sap trees and consume sap during collection.¹²⁶ In the 2005 NiV outbreak in Tangail District, Bangladesh, drinking raw date palm sap was the only activity significantly associated with illness (64% among cases vs. 18% among controls).⁸⁷ Another route of transmission for NiV from bats to people in Bangladesh could be via domestic animals. Contact with a sick cow in Meherpur, Bangladesh, in 2001 was strongly associated with NiV infection,⁶⁸ and contact with pigs and diseased goats have also been implicated in other occurrences of NiV in Bangladesh.⁸⁵ Transmission via direct contact with NiV-infected bat secretions also appears possible from evidence in the Goalando

outbreak in 2004, where individuals who climbed trees were more likely to develop NiV infection than controls.⁹⁹

The mode of transmission from bats to spillover hosts in Australia and Malaysia remains to be determined. Three principal hypotheses exist. One is that masticated pellets of virus-contaminated, residual fruit pulp spat out by flying foxes are ingested by horses or pigs.¹⁶⁴ The second is that urine from infected animals contaminates pastures or pigsties. The third is that infected fetal tissues or fluids contaminate pastures or sties and are ingested. The latter is based largely on the fact that the HeV outbreaks have occurred during the birthing period of some species of flying fox and is supported by the isolation of virus from a pregnant flying fox and its fetus.⁵⁶

HeV has been transmitted from horse to man on seven occasions from 1994 to 2009, twice during the initial outbreak in Brisbane,⁴ twice during necropsy of horses that died in the field,^{125,130} twice during either daily nasal cavity lavage and participating in a necropsy,¹¹⁵ and once from performing an endoscopy on an infected horse.⁶ HeV is rarely found in the bronchi or bronchioles of infected horses, which suggests that aerosol transmission to either man or horses is less likely⁶⁴ and horse-to-horse transmission of HeV has not been demonstrated.¹⁵⁶ The presence of HeV in equine saliva, however, suggests that close contact with infected horses, such as might occur during manual feeding of the animals, may facilitate horse-to-human transmission.¹³⁰ The presence of virus in a wide range of tissues and in the nasal discharge commonly found at the terminal stage of infection offers a range of sources for virus transmission during necropsy.^{103,104} As shown in Figure 37.5A, high level of viral antigen can be detected in the nasal cavity of HeV-infected horses.

In the Malaysian NiV outbreak, contact with pigs or fresh pig products was required for transmission of the virus to humans, with greater likelihood of transfer to those in direct contact with sick or dying pigs on farms or in abattoirs.^{30,111} The presence of NiV in the respiratory epithelium of naturally and experimentally infected pigs (Fig. 37.5B) indicated that

FIGURE 37.5. Immunoperoxidase detection of viral antigen in henipavirus-infected tissues. A: Staining of Hendra virus (HeV) antigen (N protein-specific antibody) within the wall of superficial arteriole in the submucosa of the nasal cavity in a HeV-infected horse. **B:** Immunolabeling (using anti-Nipah virus rabbit serum) within the lung of a pig infected with Nipah virus. Involvement of bronchial epithelium and airway debris is noted. (Courtesy of Dr. Deborah Middleton, CSIRO Australian Animal Health Laboratory.)

virus probably spread to humans and within the pig population by aerosol or by direct contact with oropharyngeal or nasal secretions.^{95,97,149} The presence of the virus in a wide range of organs indicates that humans may also have been infected during processes such as slaughtering or farrowing. In Bangladesh, pigs were excluded as potential sources of NiV on epidemiologic grounds, and human-to-human transmission was observed.^{54,62} The virus may have been transmitted to human index cases directly through contact with fruit bat secretions in contaminated fruit or date palm sap before circulation in the human population.^{33,43,68,85} Nosocomial transmission has been detected in some of the Bangladesh and India outbreaks.^{9,23,85}

CLINICAL FEATURES

Incubation Period

Based on the time interval between the last exposure to pigs and onset of disease, the incubation period for NiV ranged from 2 to 45 days; however, for 90% of patients, it was 2 weeks or less.^{27,28,48} An estimate of 2 to 3 weeks was made based on the time interval between importation of pigs from NiV-affected areas of Malaysia and development of human disease at a Singaporean abattoir.²⁵ A mean incubation period of 9.4 days was calculated for four patients who had a fixed period of exposure.²⁷ In the occurrence of HeV in Australia in 2008, a detailed examination of exposure histories from two infected patients (one fatal) suggested a likely incubation period of 9 to 16 days, with exposure occurring some 3 days before the onset of symptoms of HeV infection in the horse.¹¹⁵

Acute Clinical Features

The first two patients infected with HeV presented with myalgia, headaches, lethargy, and vertigo. One patient recovered; however, the other developed pneumonitis, respiratory failure, renal failure, and arterial thrombosis, and died of cardiac arrest 7 days after admission to the hospital. Findings at autopsy were consistent with a viral infection; both lungs were congested, hemorrhagic, and filled with serous fluid, and the histology revealed focal necrotizing alveolitis with many giant cells, some syncytial formation, and viral inclusions.¹³⁰ A third case of HeV infection presented first with meningitis and a 12-day history of sore throat, headache, drowsiness, vomiting, and neck stiffness. After an apparent full recovery, this patient developed fatal encephalitis 13 months later and was admitted to the hospital with a generalized tonic-clonic seizure after 2 weeks of irritable mood and low back pain. Recurrent focal motor seizures occurred over the next 7 days, as did secondarily generalized seizures and low-grade fever, followed by dense right hemiplegia, signs of brain stem involvement, and depressed consciousness requiring intubation. The patient remained comatose and died 25 days after admission.¹⁰⁷ Two patients in 2008¹¹⁵ presented with initial influenza-like illness, although soon after apparent clinical improvement and an absence of fever, encephalitis developed in both. Magnetic resonance imaging (MRI) revealed widespread cortical, subcortical, and deep white matter involvement, similar to the previous late-onset case of HeV encephalitis¹⁰⁷ and to NiV encephalitis cases.^{78,127}

With NiV, the mean duration of illness from the onset of symptoms to the nadir was 3 to 31 days, with an average of 6.9 days.⁴⁸ Most patients presented with acute encephalitis

characterized by fever, headache, drowsiness, dizziness, myalgia, and vomiting, and more than 50% had a reduced level of consciousness.^{27,30,48,114} The major clinical signs included drowsiness, areflexia, segmental myoclonus, tachycardia, hypertension, pinpoint pupils, and an abnormal doll's eye reflex. Such clinical features as these suggested involvement of the brain stem and upper cervical spinal cord, and were observed more frequently in patients with a reduced level of consciousness.^{48,139} Patients who retained normal levels of consciousness throughout their illness recovered fully; however, only 15% with reduced levels of consciousness survived. Such neurologic manifestations are consistent with vasculitis-induced thrombosis in the brain and the direct infection of neurons.^{29,30,114,159} The multiple discrete lesions 1 to 5 mm in diameter in the cerebral white matter detected by MRI may be the site of such microinfarctions and are distinct from lesions caused by other viruses.^{30,82,114,127,159} Although the predominant clinical features of NiV encephalitis derive from CNS involvement, a proportion of patients displayed pulmonary involvement, which presented as an atypical pneumonia with fever, cough, and headache.^{27,48,114} The clinical presentation of NiV infections in Bangladesh is also predominantly a severe respiratory disease.⁶⁷

Outcome of Infection

Most patients who survived acute NiV encephalitis made a full recovery; however, approximately 20% had residual neurologic deficits.^{27,48,83} Neurologic sequelae included cognitive difficulties, tetraparesis, cerebellar signs, nerve palsies, and clinical depression. A few patients remained in a vegetative state. In patients with encephalitis who recovered, most brain lesions revealed by MRI disappeared or became smaller over a period of 12 to 18 months, although some remained unchanged during this period.⁸³ Approximately 7.5% of patients who recovered from acute encephalitis and 3.4% of those who experienced nonencephalitic or asymptomatic infection developed late neurologic disease.^{48,127,138,161} Relapse encephalitis and late-onset encephalitis presented several months to 4 years after the initial infection. Relapsed cases had elevated IgG, but not IgM, and no vasculitis, and unlike the situation in acute encephalitis, virus was not isolated from throat and nasal secretions.^{30-32,127,159,161}

The clinical features associated with relapse and late-onset encephalitis resembled those found with acute NiV encephalitis, although decreased incidence was seen of fever, coma, segmental myoclonus, and meningism and an increased occurrence of seizures and focal cortical signs compared with the acute manifestation of the disease.¹³⁸ The clinical, radiologic, and pathologic features of relapse NiV encephalitis resembled those of the patient who became infected with HeV, suffered mild, transient aseptic meningitis, and recovered but died of a fatal meningoencephalitis 13 months later.^{107,158} Most patients with relapse and late-onset encephalitis had only one neurologic episode, although some patients experienced two episodes separated by a mean of 7.6 months (6 weeks to 1 year).¹³⁸ The mortality rate associated with relapse and late-onset encephalitis at 18% was lower than that associated with acute encephalitis, at 30% to 40%. However, 61% of patients with relapse and late onset had further neurologic sequelae compared with 22% after acute encephalitis. Among NiV survivors in Bangladesh, some 30% have moderate to severe persistent neurologic dysfunction for years following acute infection.¹²⁸

The demographics, clinical features, serology, and MRI of patients with relapsed and late-onset encephalitis were similar, suggesting that the two diseases have identical pathogenesis¹³⁸ and that the initial infection in late-onset encephalitis patients may not have been sufficiently severe to cause neurologic symptoms. MRI abnormalities similar to those observed in patients with acute encephalitis were also seen in 16% of asymptomatic patients, although the lesions were fewer in number.¹³⁹ The involvement of the cortex in relapse and late-onset encephalitis suggests a different pathologic mechanism compared with acute encephalitis. Relapse and late-onset encephalitis are considered to be caused by the recrudesence and rapid replication of virus that had persisted following acute or asymptomatic NiV infection.¹³⁸ NiV, however, was not isolated from CSF and brain tissue of patients with relapse and late-onset encephalitis.¹³⁸

DIAGNOSIS

Laboratory Diagnosis

Virus isolation, EM, immuno-EM, immunohistochemistry (IHC), serology, and polymerase chain reaction (PCR) played key roles in the initial discovery of HeV¹⁰⁴ and NiV,²⁹ and they remain essential elements in a repertoire of procedures for the rapid and specific diagnosis of henipavirus infections in humans and animals.

During investigation of a suspected disease outbreak, attempts to grow henipaviruses may be initiated in a BSL3 laboratory. However, if a cytopathic effect (CPE) is observed and the growth of henipavirus is confirmed by PCR or immune staining, infected cultures should be handled under BSL4 conditions and subsequent work with live virus restricted to BSL4. Both HeV and NiV replicate in various cell lines—a feature that contributed to the efficiency with which they were isolated during the initial disease outbreak investigations.^{29,104} Vero cells are commonly used, generating titers of virus as high as 10^8 infectious virions per milliliter.^{28,34} In fatal cases, attempts should be made to isolate virus from brain, lung, kidney, and spleen.³⁴ For tissue specimens containing a high virus load, direct examination by immuno-EM and IHC can be very useful in providing early diagnosis. Various antibody reagents have been developed for this purpose, including polyclonal antisera, monospecific antibodies raised against recombinant antigens,¹⁴⁷ and monoclonal antibodies (mAb) raised against whole virions or vaccinia virus-expressed viral proteins.^{71,140,141,153} Using HeV- or NiV-specific mAb, it is possible to differentiate between the two viruses.^{141,153} Quantitative real-time PCR (TaqMan assay) has been the method of choice to detect viral materials in infected tissues because of its speed, specificity, and sensitivity. The first-generation henipavirus TaqMan assays are either HeV specific¹⁵⁴ or NiV specific.⁵² Recently, several consensus henipavirus real-time PCR assays have been developed that target different conserved regions of the viral genome.⁴¹ It should be cautioned that the current PCR tests may not work with new henipaviruses yet to be discovered, especially those from African bats, owing to expected greater genetic divergence than those detected in Australia and Asia.

For henipaviruses, serologic tests are important both during outbreak investigation and for disease surveillance. The virus neutralization test (VNT) is accepted as the reference standard.³⁴ Few laboratories, however, can conduct neutralization

tests because of the requirement to handle live virus at BSL4. For surveillance and diagnostic purposes, three types of tests that do not require BSL4 containment have been developed:

1. *Enzyme-linked immunosorbent assay (ELISA)*: Several ELISA-based tests have been reported for the detection of henipavirus antibodies.^{34,40,73} For diagnosis of human infections, two different ELISA tests have been applied: an IgM capture ELISA for early diagnosis of infection and an indirect ELISA for detection of IgG antibodies.³⁴
2. *Liquid protein array multiplex test*: A Luminex-based test based on recombinant soluble G proteins of HeV and NiV was developed that is capable of mimicking VNT with great sensitivity and differentiating between antibody responses of HeV versus NiV infection.¹⁵
3. *Pseudotype virus*: Different pseudotype systems carrying the henipavirus F and G proteins have been developed as a surrogate VNT for detecting henipavirus-specific antibodies.^{72,74,137} Incorporation of reporter genes in these systems resulted in greater sensitivity and reproducibility.^{72,137}

PREVENTION AND CONTROL

Treatment

Ribavirin, which inhibits replication of HeV *in vitro*,¹⁶² was used during the NiV outbreak in Malaysia in an open-label study in which 140 patients with encephalitis were given the drug, and 54 patients who presented before ribavirin became available or who refused treatment acted as controls.²⁶ Mortality in the treated group was 32% compared with 54% in the control group, representing a 35% reduction ($P = 0.011$). Duration of ventilation and total hospital stay were both significantly shorter in the ribavirin group ($P = 0.0002$ and <0.0001 , respectively). In the absence of other therapies, ribavirin may be an option for treatment of henipavirus infections. However, two HeV-infected patients in 2008¹¹⁵ were given a high-dose intravenous regimen of ribavirin, although basal concentrations appeared inadequate given the results of *in vitro* susceptibility testing of HeV, and the efficacy of ribavirin as therapy or prophylaxis in people remains at best uncertain. Chloroquine, an antimalarial drug, was first demonstrated to block the critical proteolytic processing needed for HeV F maturation and function.¹⁰⁹ Not surprisingly, the drug was later shown to inhibit NiV and HeV infection in cell culture experiments.¹¹⁷ Chloroquine was administered along with ribavirin to one HeV-infected individual in 2009⁶ with no apparent clinical benefit.

In vivo, ribavirin only delayed but did not prevent deaths caused by NiV and had no effect on HeV infection in a hamster model.^{44,47} Ribavirin treatment also only delayed disease onset by 1 to 2 days in African green monkeys challenged with HeV with no significant benefit for disease progression or outcome.¹²¹ Chloroquine administration, either alone or in combination with ribavirin, had no therapeutic benefit in ferrets challenged with NiV or hamsters challenged with either NiV or HeV.^{44,110}

Vaccines and Passive Immunotherapy

No henipavirus vaccines are available at this time; however, studies suggest that vaccination may offer several viable anti-henipavirus strategies.^{22,38} NiV F and G glycoproteins expressed from vaccinia virus elicit neutralizing antibodies in mice and

hamsters,^{51,136} with higher antibody titers generated in response to the G glycoprotein compared with the F glycoprotein. Hamsters were protected from lethal challenge with NiV following vaccination with vaccinia virus expressing either NiV F or G glycoprotein.⁵¹ The challenge virus was capable of hyperimmunizing vaccinated animals, indicating that although the virus replicated, the presence of neutralizing antibodies ameliorated replication to an extent that limited infection and prevented clinical disease. Further, the protection afforded hamsters by passive transfer of anti-G and anti-F antibodies before a lethal NiV or HeV challenge confirmed both the importance of a humoral protective immune response to NiV.^{51,53}

HeV G glycoprotein has been expressed in a soluble form (sG-HeV) that retains many native characteristics and can elicit a potent cross-reactive neutralizing antibody response in rabbits.¹⁴ Rabbit anti-HeV G antibodies neutralize both HeV and NiV in cell culture, displaying a slightly higher titer against the homologous virus. The nature and location of the neutralizing epitopes on the F glycoprotein have not been reported, although preliminary information is available for the HeV G glycoprotein.¹⁵³ Four neutralizing epitopes have been mapped on the globular head of the HeV G protein. Two are located on the base of the head and two on the top, in locations resembling those identified as neutralizing sites in other paramyxoviruses.

Immunization and challenge studies using recombinant sG-HeV in the cat model have demonstrated that the protein can illicit a completely protective immune response against NiV challenge,¹⁰¹ even at a low-dose formulation with CpG and Alhydrogel and a two-dose protocol followed by oronasal challenge with 50,000 TCID₅₀ of NiV.⁹¹ Further sG-HeV immunization studies have been completed in the ferret with a HeV challenge (J. Pallister and L-F. Wang, in submission) and in the African green monkey with a NiV challenge (T. Geisbert and C. Broder, in submission). In both of these investigations, complete protection from henipavirus-induced disease was achieved. The potential application of sG-HeV as an equine vaccine is being evaluated in Australia (D. Middleton, personal communication). These data suggest that a single vaccine (sG-HeV) may be effective against both HeV and NiV. Analysis of the antibody responses in sera from naturally infected or immunized sources has also shown that HeV-infected sources had high levels of NiV G cross-reactive antibodies, whereas NiV-infected individuals had limited cross-reactive antibodies to HeV G. Together, these data suggested that the HeV G stimulates a more cross-reactive immune response.¹⁵

The sG-HeV glycoprotein was also used to isolate HeV G-specific human mAbs. One human mAb (m102.4) was HeV and NiV cross-reactive and possessed extremely potent virus neutralizing activity.^{167,168} *In vivo* studies have demonstrated that m102.4 can protect animals from a lethal challenge with henipavirus as a postexposure application in the ferret model with NiV¹⁹ and in the African green monkey model with HeV (T. Geisbert and C. Broder, in submission). In August 2009, m102.4 was used on a compassionate basis to save the life of an HeV-infected individual while in a coma (G. Playford, personal communication). Unfortunately, delivery and intravenous administration of only 100 mg of available antibody occurred after the onset of encephalitis, and the individual died shortly thereafter. During the 2010 HeV emergence, 11 people had potential exposure and 2 individuals considered at high risk. In this instance, the m102.4 antibody was given to 2 individu-

als prior to HeV diagnosis or the onset of clinical disease⁵ at doses sufficient to achieve a high serum concentration. Both individuals have remained healthy. Altogether, these findings highlight the therapeutic potential of antibody-based passive transfer modalities for treating henipavirus exposure.

Peptide Inhibitors

The first potential henipavirus-specific therapeutic was shown to be a heptad peptide-based fusion inhibitor¹⁷ analogous to the human immunodeficiency virus type 1 (HIV-1)-specific peptide, enfuvirtide (Fuzeon) approved by the Food and Drug Administration (FDA) in March 2003. The henipavirus F₁ glycoprotein resembles other fusion glycoproteins in having α -helical heptad repeat (HR) domains proximal to both the fusion peptide at the amino (N) terminus and the transmembrane domain near the carboxy (C) terminus of the protein. The HR domains are involved in the formation of a trimer-of-hairpins structure during or immediately following the fusion of virus and cell membranes that occurs during infection. Addition of exogenous peptide from either HR domain blocks formation of the trimer-of-hairpins and abrogates membrane fusion and entry of the viral genome into the cell.^{16,17,38} These observations were followed up with testing cholesterol tagged HR-derived peptides in the hamster model of NiV infection.¹¹⁸ The *in vivo* efficacy of peptide fusion inhibitors of henipavirus infection merits further investigation.

PERSPECTIVE AND GEOGRAPHIC CONSIDERATIONS

The high virulence of the henipaviruses and the requirement for BSL4 facilities have hampered investigations into the biology and pathogenesis of these novel paramyxoviruses. Recent investigations into the structure and function of henipavirus proteins expressed from cloned genes have provided insight into the functions of many henipavirus proteins in infected cells. It remains to be determined if all of the functional characteristics of the henipavirus proteins determined *in vitro* accurately reflect the role that they play in the cells of both terrestrial and chiropteran hosts.

Many questions relating to the ecology and biology of henipaviruses remain unanswered. Little doubt exists that *Pteropus* species of fruit bats are the major reservoir host of these viruses. With the wide geographic range of *Pteropus* species as overlapping populations, extending from islands in the South Pacific through Australia, and southern Asia to Pakistan, and with additional species on islands off the eastern coast of Africa, together with the cross-reactive serologic evidence of henipavirus presence,^{61,81} it would seem that several other related viruses may remain to be identified.^{43,56} The emergence of these and related viruses is probably associated with the destruction of the flying fox native habitats, driving the animals to seek food from orchards and ornamental trees in urban and periurban areas. Thus, with continued deforestation, undoubtedly further outbreaks of HeV, NiV, and novel related members of the genus will occur. The mechanisms by which henipaviruses are transmitted between fruit bats and maintained within their colonies, as well as the pathways leading to the infection of spillover hosts, remain to be elucidated.

from infants with respiratory illness, and serologic studies indicated that infection in infants and children was common.^{86,87} HRSV is now recognized as the most important viral agent of pediatric lower respiratory tract illness (LRI) worldwide. In many areas it outranks other microbial pathogens as a cause of pneumonia and bronchiolitis in infants. In addition, HRSV can infect and cause disease in individuals of all ages and severe disease in the elderly and in profoundly immunosuppressed individuals.^{146,163,233} Worldwide, acute respiratory infection (ARI) is the leading cause of mortality due to infectious disease, and HRSV remains one of the pathogens deemed most important for vaccine development. HRSV research is hampered by its poor growth *in vitro* and its physical instability. HRSV has a single serotype with two antigenic subgroups A and B.

Human metapneumovirus (HMPV) was first described in 2001 following its isolation from infants and children experiencing HRSV-like disease of unknown etiology.⁵⁷² There is serologic evidence of extensive pediatric infection dating back more than 50 years, and thus HMPV is newly discovered rather than newly emerged.^{572,608,610} The virus had been overlooked because it grows slowly *in vitro*, has a delayed cytopathic effect, and usually requires added trypsin for activation of the fusion F protein. HMPV is recognized as an important agent of respiratory tract disease worldwide, especially in the pediatric and elderly populations, although its impact is less than that of HRSV.⁶⁰⁸ HMPV also has a single serotype with two subgroups A and B.⁵¹⁵

INFECTIOUS AGENT

Classification

HRSV and HMPV are enveloped, cytoplasmic viruses with single-stranded nonsegmented negative-sense RNA genomes. They are members of the family *Paramyxoviridae* (Chapter 33) of the order *Mononegavirales* (Chapter 30). *Paramyxoviridae* has two subfamilies: *Paramyxovirinae*, which includes the human and animal parainfluenza viruses (PIVs, Chapter 34), mumps virus (Chapter 35), and measles virus (Chapter 36) among others, and *Pneumovirinae*, which consists of HRSV and HMPV and their animal relatives. There are two genera in *Pneumovirinae*: Genus *Pneumovirus* consists of HRSV, bovine RSV (BRSV), and pneumonia virus of mice (PVM), and genus *Metapneumovirus* consists of HMPV and avian metapneumovirus (AMPV, formerly called turkey rhinotracheitis virus [TRTV] or avian pneumovirus [APV]). Comparisons of

HISTORY

Human respiratory syncytial virus (HRSV) was first isolated in 1955 from a laboratory chimpanzee with illness resembling the common cold.³⁹⁸ Shortly thereafter, the same virus was recovered

FIGURE 38.1. Idealized diagram of the human respiratory syncytial (HRSV) particle. The G, SH, and F proteins are present in homo-oligomers that constitute the glycoprotein spikes. The M protein underlies the lipid bilayer. The proteins of the nucleocapsid are not depicted individually. The human metapneumovirus (HMPV) particle is similar.

these viruses based on gene maps and nucleotide sequences are shown [e-Figures 38.1 and 38.2](#).

(Note that the descriptions in the following sections usually will begin with HRSV followed by HMPV.)

Virion

The HRSV virion consists of a nucleocapsid that is packaged in a lipid envelope derived from the host cell plasma membrane during budding (Fig. 38.1 and Fig. 38.2C). When visualized by electron microscopy (Fig. 38.2C and E), virions appear as irregular spherical particles of 100 to 350 nm in diameter and long filamentous forms that often predominate and are 60 to 200 nm in diameter and up to 10 μ m in length. Despite the variability in size and shape, the ultraviolet (UV) inactivation kinetics of infectivity indicates that most particles contain a single functional genome.¹⁴⁰ Both forms of the virion mostly remain cell associated. The filaments can be visualized as projections from the surface of infected cells by fluorescence photomicroscopy^{19,270,423,475} (Fig. 38.2B). The nucleocapsid appears in electron micrographs as a herringbone structure that is characteristic of *Paramyxoviridae*. However, the HRSV nucleocapsid is narrower than those of prototype members of *Paramyxovirinae* (12 to 16 nm compared to 17 to 20 nm) and has a steeper pitch.^{19,42,423}

The HRSV envelope contains three virally encoded transmembrane surface glycoproteins: the major attachment protein G, the fusion protein F, and the small hydrophobic (SH) protein (Figs. 38.3A and 38.4). In addition, there is a nonglycosylated matrix M protein that is thought to form a layer on the inner face of the envelope. The viral glycoproteins are present as transmembrane homooligomers that are visualized as short (11 to 20 nm), closely spaced (intervals of 6 to 10 nm) surface projections or “spikes.” HRSV lacks a neuraminidase or a hemagglutinin; PVM alone agglutinates murine erythrocytes, via its G protein.³³⁹

The viral RNA is associated with four nucleocapsid/polymerase proteins: the nucleoprotein N, the phosphoprotein P, the transcription processivity factor M2-1, and the large polymerase subunit L (Fig. 38.3A). However, polymerase activity in purified virions, an activity found in prototypic

members of *Mononegavirales*, has not been demonstrated for HRSV preparations.

HRSV virions can readily lose infectivity during handling, presumably reflecting particle instability. This can be partly overcome by agents such as sugars that reduce aggregation and improve thermal stability.¹⁷ When recombinant HRSV was engineered to contain a foreign attachment protein from baculovirus in place of the HRSV glycoproteins, the stability of infectivity was improved,⁴⁹¹ suggesting that the lability of the particle may reside in one or more of the glycoproteins. Other data have implicated the F protein in thermo instability.⁴⁶⁹ The long filamentous shape of the particle may also contribute to fragility and loss of infectivity.

HMPV virions were visualized by electron microscopy as pleomorphic spheres and filaments that appear to have general similarity to those of HRSV^{443,572} (Fig. 38.2F). The spherical particles had a reported diameter of 150 to 600 nm with envelope spikes of 13 to 17 nm. The nucleocapsid diameter was reported as 17 nm, suggesting a possible difference compared to HRSV.⁴⁴³ HMPV appears to lack a hemagglutinin⁵⁷²; other virion-associated activities have not been reported. HMPV has the same array of structural proteins as HRSV (Fig. 38.3B). The infectivity of HMPV particles is markedly more stable than that of HRSV.⁵⁵⁷

RNA

The HRSV genome (Fig. 38.3C) is a single negative-sense strand of RNA ranging in length from 15,191 to 15,226 nucleotides for six sequenced strains including the subgroup A strains A2 (15,222 nucleotides; GenBank accession number M74568), Long (15,226 nucleotides; AY911262), S2 (15,191 nucleotides; NC_001803), and line 19 (15,191 nucleotides; FJ614813), and the subgroup B strains B1 (15,225 nucleotides; NC_001781) and 9320 (15,225 nucleotides; AY353550). More recently, complete sequences were reported and analyzed for 60 and four additional subgroup A and B strains, respectively.^{313a,491a,538a} In addition, extensive sequence information and extensive inter-subgroup comparison is available for subgroup B strain 18537.^{274,276,278} The genome is neither capped nor polyadenylated. Both in virions and intracellularly, the genome is tightly and completely bound by N protein to create an RNase-resistant nucleocapsid, as is typical of *Mononegavirales*. This tight encapsidation likely protects the genome, which lacks stabilizing features of capping and polyadenylation, from degradation. It also likely shields the genome from recognition by host cell pattern recognition receptors, especially (a) the cytoplasmic helicases retinoic acid-inducible gene I (RIG-I) and melanoma differentiation-associated protein (MDA-5), which detect triphosphorylated RNA and double-stranded RNA (dsRNA) and activate the cellular transcription factors interferon regulatory factor 3 (IRF3) and nuclear factor kappa B (NF- κ B) to induce type I interferon (IFN) and proinflammatory cytokines, and (b) RNA-inducible protein kinase R (PKR), which also activates NF- κ B and phosphorylates eukaryotic translation initiation factor 2a (eIF-2a) to inhibit translational initiation as part of antiviral defense.

The HRSV genome contains 10 genes in the order 3' NS1-NS2-N-P-M-SH-G-F-M2-L (Fig. 38.3C) that are transcribed sequentially into 10 separate messenger RNAs (mRNAs).^{95,99,107,140,388} Each gene begins with a highly conserved nine-nucleotide gene-start (GS) transcription signal and ends with a moderately conserved 12- to 13-nucleotide

gene-end (GE) signal^{275,315} (e-Fig. 38.3A). The first nine genes are separated by intergenic regions that vary in length from 1 to 58 nucleotides for the strains sequenced to date.²⁷⁵ These lack any conserved motifs, are poorly conserved between strains, and appear to be unimportant spacers. The last two HRSV genes, M2 and L, overlap by 68 nucleotides¹⁰⁶ (Fig. 38.3C and e-Fig. 38.3A). Specifically, the GS signal for the L gene is located upstream, rather than downstream, of the M2 GE signal. The same overlap occurs in BRSV; overlapping genes are not found in any other members of *Paramyxoviridae*, but sometimes are

found in *Rhabdoviridae* and *Filoviridae*. The 3′ and 5′ ends of the genome consist of short extragenic leader and trailer regions (44 and 155 nucleotides long, respectively, in strain A2).

The HRSV mRNAs contain a methylated 5′ cap structure m⁷G[5′]ppp[5′]Gp²⁴ and are polyadenylated by reiterative copying on a U tract in the GE signal. Each HRSV mRNA encodes a single major protein except for M2, which has separate open reading frames (ORFs) for the M2-1 and M2-2 proteins. The M2-1 ORF is located in the upstream part of the mRNA, whereas the M2-2 ORF is located downstream and

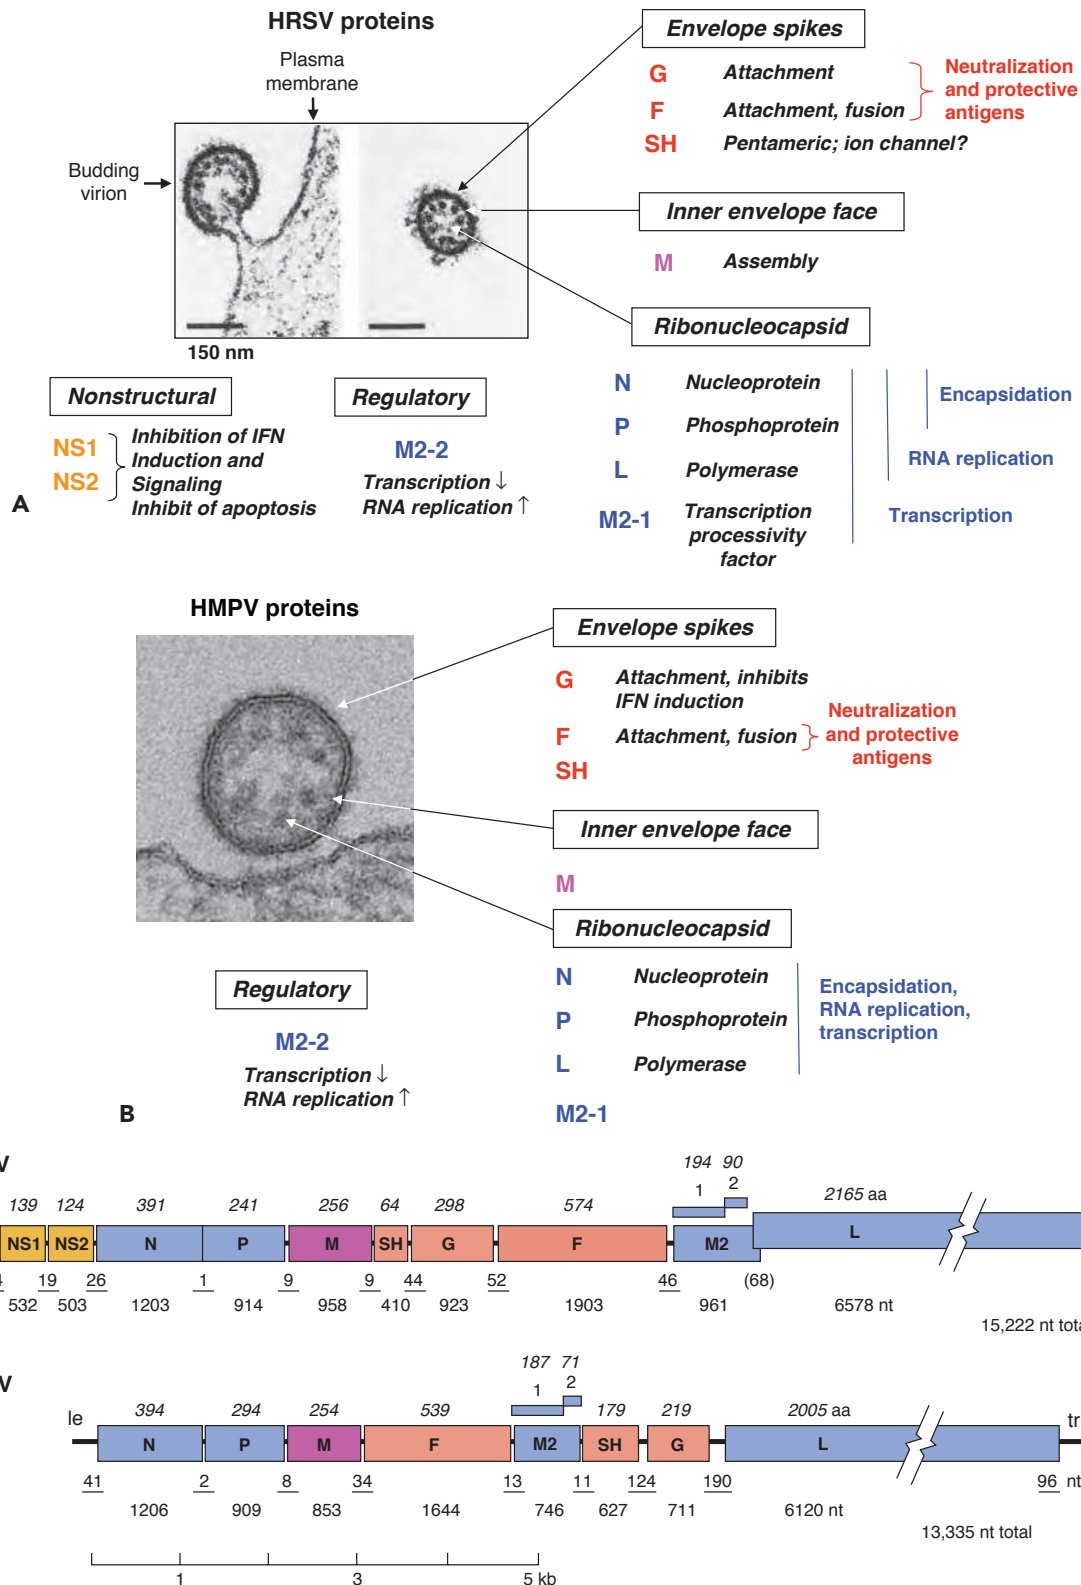

FIGURE 38.3. The proteins of human respiratory syncytial virus (HRSV) (A) and human metapneumovirus (HMPV) (B), and maps of the viral genomic RNAs (C). **A** and **B**: Locations of the proteins in the virus particle and major functions are indicated when known. **A–C**: Color-coded: proteins/genes of the nucleocapsid and polymerase complex or that are involved in RNA synthesis are in blue, surface glycoproteins in red, matrix protein in magenta, and the two HRSV nonstructural proteins in brown. The maps in **panel C** are approximately to scale and show the 3' to 5' negative-sense genomes of HRSV strain A2 and HMPV strain CAN97-83. The overlapping open reading frames (ORFs) of the M2 messenger RNAs (mRNAs) are illustrated over the M2 genes. Numbers beneath each map indicate nucleotide (nt) lengths; those of the extragenic leader (le), trailer (tr), and intergenic regions are underlined, and that of the HRSV gene overlap is in parentheses. *Italicized numbers* above each map indicate amino acid (aa) lengths.

FIGURE 38.4. Primary structures (approximately to scale) of the F, G, and SH surface glycoproteins of human respiratory syncytial virus (HRSV) strain A2 and human metapneumovirus (HMPV) strain CAN97-83. Hydrophobic domains are brown bars: Sig., signal peptide; FP, fusion peptide; TM, transmembrane anchor; CT, cytoplasmic tail. Heptad repeats (HR) in the F protein are green and cysteine residues conserved between the F proteins of HRSV and HMPV are indicated underneath (indicated as c). Downward-facing arrows identify the cleavage-activation site(s) in the F protein. Potential acceptor sites for N-linked carbohydrate are indicated as downward facing stalks with N. For each G protein, the 25 potential acceptor sites for O-linked sugars predicted by NetOGlyc 2.0 to be the most likely to be utilized are indicated as downward facing stalks with small circles. The sequence excerpt above the HRSV G protein shows the conserved segment (underlined) and cysteine noose; cysteine residues are bold; the disulfide bonding pattern is indicated by dotted lines²⁰¹; and the fractalkine CX3C motif is boxed. M-48 in the HRSV G protein is the translational start site for the secreted form, and the mature secreted form is indicated.⁴⁷⁶

overlaps by 32 nucleotides in strain A2. Translation of the downstream M2-2 ORF depends on reinitiation by ribosomes exiting the upstream M2-1 ORF, a process that appears to be influenced by the structure of a region of RNA located ~150 nucleotides upstream of the M2-2 translational start site.^{202,203} Whereas the P genes of *Paramyxovirinae* encode additional accessory proteins by overlapping ORFs, alternative translational start sites, and RNA editing (Chapter 33), the P gene of HRSV (and HMPV) encodes only P.

HRSV transcription follows the general *Mononegavirales* model^{111,140,316} (Chapters 31 and 33), involving initiation at a single 3' promoter and a start-stop-restart sequential mechanism guided by the GS and GE signals. RNA sequences important in transcriptional initiation are shown in e-Fig. 38.4. Capping seems to be an essential step for efficient mRNA elongation: when capping was blocked using a novel HRSV-specific inhibitor, transcription produced uncapped abortive RNAs of ~45 to 50 nt.³⁴³ Termination at the various GE signals typically is somewhat inefficient, resulting in readthrough transcription that creates mRNAs representing two or more adjacent genes

and their intervening intergenic regions.¹⁰⁷ These readthrough mRNAs account for approximately 10% of total mRNA.

The M2/L gene overlap raises two questions for the model of sequential transcription: (a) how do polymerases that exit the M2 gene find the upstream L GS signal (or does polymerase enter independently at that site), and (b) how do polymerases that initiate at the L GS signal avoid premature termination when they cross the M2 GE signal? Studies with a minireplicon system showed that when polymerase completes transcription of the M2 gene, it efficiently gains access to the L gene by retrograde scanning.¹⁷⁰ The polymerase appeared to scan in both directions. This led to the realization that scanning may be a common function of the polymerase, and may occur at each gene junction as well as prior to the initiation of transcription and RNA replication. The M2 GE signal within the L gene indeed causes premature termination for 90% of L gene transcripts, producing a 68-nucleotide polyadenylated RNA that does not appear to encode a protein and is not known to have any further significance.¹⁰⁶ The synthesis of full-length L mRNA depends on polymerase readthrough at

the M2 GE signal. Therefore, the “error” of reading through a GE signal is necessary for synthesis of this essential mRNA.¹⁰⁶ Premature termination of 90% of L gene transcripts might be expected to severely downregulate the production of full-length mRNA, but the ability of the polymerase to recycle back to the L GS signal apparently relieves much of this effect, and the amount of L mRNA produced for HRSV relative to the other mRNAs appears to be about the same as for other members of *Paramyxoviridae*. The gene overlap does not seem to be of any particular benefit to the virus, and may be an accidental arrangement that can be tolerated due to the scanning function of the polymerase.

RNA replication by HRSV also follows the general *Mononegavirales* model (Chapters 31 and 33). RNA sequences important in the initiation of RNA replication are shown in e-Fig. 38.4. The replicating polymerase ignores the GS and GE signals and produces a complete positive-sense copy of the viral genome that is called the antigenome and that also is tightly encapsidated. The antigenome serves in turn as the template for producing progeny genomes. Chain elongation of nascent genomes and antigenomes depends on concurrent encapsidation.³⁷³ For viruses in the subfamily *Paramyxovirinae*, the nucleotide length of the genome must be an even multiple of six in order for efficient RNA replication to occur (“rule of six”; Chapter 33), reflecting a requirement for nucleocapsid organization, but there appears to be no comparable requirement for members of *Pneumovirinae*.^{303,488}

The HMPV genome is approximately 13.2 kb—nearly 2 kb shorter than that of HRSV—and lacks the NS1 and NS2 genes (Fig. 38.3C). In addition, the order of the SH, G, F, and M2 genes differs between HRSV (SH-G-F-M2) and HMPV (F-M2-SH-G). Correcting for the lack of NS1 and NS2 for HMPV and the difference in gene order, the genomes of HRSV and HMPV share 50% nucleotide sequence identity. Strains for which complete sequences have been reported include the following: CAN97-83 (13,335 nt, GenBank accession AY297749) and NL/00/1 (13,350, AF371337) of subgroup A, and CAN98-75 (13,280, AY297748) and NL/1/99 (13,293, AY525843) of subgroup B.^{46,259}

Features of the structure, encapsidation, transcription, and replication of the HMPV genome are generally similar to those described above for HRSV. The cis-acting signals of HMPV have considerable similarity to those of HRSV^{46,571} (e-Fig. 38.3B). The HMPV intergenic regions can be longer than those of HRSV, up to 190 nt in the case of CAN97-83 (Fig. 38.3C and e-Fig. 38.3B). Unlike HRSV, the HMPV M2-2 protein appears to be translated independently of the upstream M2-1 ORF.⁶⁶

Proteins

HRSV encodes 11 separate proteins (Fig. 38.3A). HMPV encodes nine proteins (Fig. 38.3B) that generally correspond to those of HRSV except for the lack of NS1 and NS2.^{46,571} Table 38.1 shows amino acid sequence relatedness between viruses within subfamily *Pneumovirinae*.

Fusion F Glycoprotein

The HRSV F and L proteins are the ones that most closely resemble their counterparts in *Paramyxovirinae*. As is typical for *Paramyxoviridae*, the HRSV F protein directs viral penetration by fusion between the virion envelope and the host cell plasma membrane. Later in infection, F protein expressed on the cell surface can mediate fusion with neighboring cells to form syncytia (Fig. 38.2A). Recent findings suggest that the HRSV F protein also plays a major role in viral attachment involving interaction with the cellular protein nucleolin.⁵⁴³

F is a type I transmembrane surface protein that has a cleaved signal peptide at the N-terminus and a membrane anchor near the C-terminus¹⁰⁰ (Fig. 38.4). A predicted three-dimensional structure of the prefusion form of the HRSV F protein has been described based on homology modeling with the crystal structure of the Newcastle disease virus F protein,⁵¹⁷ and crystal structures representing the postfusion form have recently been published.^{378,536} The structure of the *Paramyxoviridae* F protein is described in detail in Chapter 33.

As is typical for *Paramyxoviridae*, F is synthesized as an inactive F0 precursor that assembles into a homotrimer.⁷⁴ HRSV F is activated by cleavage in the trans-Golgi complex by furin or a furin-like cellular endoprotease to yield two

disulfide-linked subunits: NH₂-F₂-F₁-COOH.^{103,531} The N-terminus of the F₁ subunit that is created by this cleavage contains a hydrophobic domain (the fusion peptide) that inserts directly into the target membrane to initiate fusion. The F₁ subunit also contains two areas of heptad repeats that associate during fusion, driving a conformational shift that brings the viral and cellular membranes into proximity^{100,633} (Chapter 33). HRSV F protein can direct efficient fusion independent of other viral proteins.²⁸³ This differs from the situation for most members of *Paramyxovirinae*, for which efficient fusion requires interaction with the homologous attachment protein (Chapter 33).

The F proteins of HRSV and BRSV are unique in *Paramyxoviridae* in having two cleavage sites, rather than one cleavage site^{200,636} (Fig. 38.4). The site that is immediately upstream of the fusion peptide (with cleavage between residues 136/137 in HRSV strain A2) is the one that corresponds to other *Paramyxoviridae*. This site in HRSV contains six tandem Arg and Lys residues (Lys-Lys-Arg-Lys-Arg-Arg↓). The second, novel site is located 27 amino acids upstream (with cleavage between residues 109/110) and has the sequence Arg-Ala-Arg-Arg↓. Therefore, both sites contain the preferred furin cleavage motif (Arg-X-Arg/Lys-Arg↓). HRSV F appears to be readily cleaved during intracellular processing, although some of the F protein packaged in virions remained uncleaved at site 109/110. There is indirect evidence that the double-cleavage site in the F protein is associated with a hyperfusogenic character that is linked to reduced thermostability and the ability to fuse independent of a cognate attachment protein.⁴⁶⁹

Cleavage at the two sites in F₀ releases a short peptide of 27 amino acids (p27) that contains two (strain A2) or three (strain Long) potential acceptor sites for N-linked sugars, of which at least two are utilized in strain Long.⁶³⁶ (Note that the remainder of the F protein has three acceptor sites for N-linked sugars, two in F₂ and one in F₁, all of which are utilized.⁶³⁹) For BRSV, this peptide contains a tachykinin sequence motif and is processed and released from BRSV-infected cells to yield a virokinin that induced smooth muscle contraction *in vitro*, which is a property of tachykinins.⁶³⁸ Tachykinins also have proinflammatory and immunomodulatory activities. Recombinant BRSV in which most of p27 was deleted, or in which the upstream cleavage site was mutated, replicated as efficiently as the wild-type parent in calves, but induced less pulmonary inflammation and a somewhat lower titer of serum neutralizing antibody.^{567,637} Therefore, p27 of BRSV has the potential to augment viral disease by effects on smooth muscle contraction and pulmonary inflammation, and might also stimulate the host immune response. In contrast, the sequence of p27 of HRSV does not resemble a tachykinin, and HRSV p27 did not have tachykinin-like properties *in vitro*.⁶³⁸

The HMPV F protein shares a moderate level of amino acid sequence identity with HRSV (33%)^{46,571} and is similar in general organization (Fig. 38.4). As with HRSV, HMPV F directs fusion involved in penetration and syncytium formation, and does so efficiently without need of the G and SH proteins.⁴⁸ HMPV F also appears to play a role in attachment via interaction with cellular $\alpha\beta 1$ integrin.¹¹⁸ This integrin characteristically binds to a specific recognition sequence, Arg-Gly-Asp, and this motif is present in the HMPV F protein and mediates its binding to cells.

The HMPV F₀ precursor contains only a single cleavage activation site (Fig. 38.4). The sequence at this site, Arg-Gln-

Ser-Arg↓, does not conform to the consensus furin motif and, consistent with this, clinical isolates typically require exogenous trypsin for growth *in vitro*. *In vivo*, cleavage of the HMPV F protein presumably depends on secreted protease present in the lumen of the respiratory tract. Several observations indicate that this is not a limiting factor in pathogenesis. For example, in some cases, serial passage of HMPV clinical isolates in cell culture resulted in the emergence of mutants that no longer required added trypsin, but these did not exhibit increased replication in hamsters.⁴⁹² These mutants contained the substitution of Pro in place of Ser in the -2 position of the cleavage activation site (Arg-Gln-Pro-Arg↓), which conferred intracellular cleavability even though it did not create a furin motif. Similarly, when the F cleavage site of recombinant HMPV was engineered so that it was multibasic and cleaved intracellularly, this did not increase its replication in African green monkeys (AGMs).⁴⁵

Glycoprotein G

The HRSV G protein was originally thought to be the sole viral attachment protein,³³⁴ but it now appears that the F protein also plays a role, as noted. The HRSV G protein has no apparent relatedness by sequence or structure to the attachment HN, H, and G proteins of *Paramyxovirinae* and has only half the amino acid length.^{278,597} HRSV G is a type II transmembrane glycoprotein, with a hydrophobic signal/anchor located near the N-terminus (amino acids 38-63 in strain A2) and the C-terminal two thirds of the molecule oriented extracellularly (Fig. 38.4). A secreted version of G is produced by translational initiation at the second ATG in the ORF (codon 48), which lies within the signal/anchor sequence.^{255,476} This truncated form is then trimmed by proteolysis, removing the remainder of the signal/anchor and creating a new N-terminus at Asn-66 for the final secreted form. The secreted form constituted approximately 20% of the total G protein expressed in HRSV-infected cells *in vitro*, but because of its rapid secretion it accounted for 80% of the G protein released in cell culture by 24 h post infection, the remainder being virion associated.²⁵⁵

The polypeptide backbone of HRSV G has an Mr of approximately 32,000. In the case of strain A2, an estimated four N-linked sugar side chains are added co-translationally, increasing the Mr to 45,000.^{102,598} G assembles in the endoplasmic reticulum into oligomers that probably are trimers or tetramers, and O-linked sugars are added subsequently in the trans-Golgi compartment or network.^{102,598} Mature G migrates in gel electrophoresis as a broad, seemingly heterogeneous band of Mr 80,000-90,000. Analysis of an F/G fusion protein (created as a potential vaccine) expressed in insect cells by a recombinant baculovirus indicated that G contains approximately 24-25 O-linked side chains.⁵⁹² However, when HRSV was grown in an *in vitro* model of human airway epithelium (HAE)—specifically, a differentiated pseudostratified mucociliary tissue that closely resembles the authentic airway epithelium⁶³¹—the Mr observed for the G protein was 180,000.³¹⁹ Because these cells would be considered to be a more authentic substrate than typical immortalized monolayer cultures, this suggests that the amount of carbohydrate present on G is substantially greater than previously thought. The presence of a sheath of host-specified sugars might shield the G protein from immune recognition, and might interfere with antigen processing and presentation. The secreted form of G appears to be

processed in a similar fashion to the membrane-anchored form except that it is secreted as a monomer, and no antigenic differences were detected when the secreted and membrane-bound forms were analyzed with an extensive panel of monoclonal antibodies (MAbs).¹⁵⁵

Most of the ectodomain of HRSV G consists of two large domains that are highly divergent between strains and have a “mucin-like” structure. Like mucin, these domains have a high content of serine, threonine, and proline residues; are heavily glycosylated; and are thought to have an extended, nonglobular secondary structure. Because there are more than 75 serine and threonine residues in the mucin-like domains as potential acceptor sites for O-linked sugars, there may be heterogeneity in site usage that could provide additional antigenic heterogeneity. The significance of this mucin-like character remains unknown. One possibility is that it somehow helps the virus penetrate the protective mucous layer overlying the respiratory epithelium.

The two mucin-like domains flank a central conserved domain that includes a 13-residue segment (positions 164–176 in strain A2) that is completely conserved among HRSV strains, as well as an overlapping segment containing four closely spaced invariant cysteine residues (positions 173, 176, 182, and 186)²⁷⁸ (Fig. 38.4). Disulfide linkages occur between Cys-173 and Cys-186, and between Cys-176 and Cys-182, to create a cystine noose.²⁰¹ The cysteine-rich segment contains a Cys-X₃-Cys (CX3C) motif involving Cys-182 and Cys-186 embedded in a region of limited sequence relatedness with the CX3C chemokine called fractalkine.⁵⁶¹ A peptide containing this sequence mimicked the leukocyte chemoattractant activity of fractalkine in an *in vitro* assay.

The HRSV G protein participates in viral attachment *in vitro* by binding to glycosaminoglycans (GAGs), which are long unbranched chains of repeating disaccharide subunits that are part of the glycocalyx present on the outer surface of the cell. The conserved central domain of G seemed like an obvious candidate to be involved in attachment. However, this domain can be deleted from recombinant HRSV with little effect on virus replication in HEp-2 cells or in mice.⁵⁴⁸ A study that probed for possible GAG-binding domains by evaluating interaction between peptides spanning the ectodomain of G and the GAG heparin identified a potential binding site shortly downstream from the central conserved domain,¹⁷⁵ but this also could be deleted with little effect on HRSV infection and replication *in vitro* or in mice.⁵⁴⁸ More recently, cleavage of the C-terminal domain of G was found to result in virus that bound less efficiently to GAGs and had reduced infectivity in HAE cultures, suggesting that this domain is important for the attachment function of G.³¹⁹

Extensive passage of a subgroup B strain of HRSV in AGM Vero cells—in an attempt to attenuate the virus—resulted in mutants with various spontaneous deletions involving most of the G and SH genes.²⁸⁸ One such mutant virus that was evaluated as a potential vaccine replicated efficiently in Vero cells but was highly restricted in humans. Recombinant HRSV strain A2 from which the G gene was deleted (Δ G) also replicated efficiently in Vero cells. However, the Δ G virus was restricted in HEp-2 cells, with defects at the levels of virus binding, fusion, and assembly.^{544,545,547,550} In addition, the Δ G virus was highly restricted in mice and might not have replicated at all.⁵⁵⁰ Therefore, HRSV G is dispensable for replication in Vero cells but it is essential for efficient replication in HEp-2 cells and *in vivo*.

The HMPV G protein (Fig. 38.4) has a number of similarities with HRSV G, although it lacks significant sequence identity^{46,571} (Table 38.1). HMPV G has a comparable N-terminal proximal signal/anchor domain and a high content of serine/threonine/proline residues concentrated in the ectodomain.^{46,571} In addition it is modified by the addition of N-linked and O-linked sugars to yield a mature form that migrates in gel electrophoresis as a diffuse band of Mr 97,000.³⁴¹ Its amino acid sequence also is highly divergent between the HMPV subgroups. However, HMPV G lacks the conserved central domain and cystine noose mentioned above for HRSV and is correspondingly shorter in length. A secreted form of HMPV G has not been described, and the amino acid sequence gives no suggestion that such a species exists. As with HRSV, the HMPV G protein binds to cell surface GAGs, which may reflect its role in attachment.⁵⁵¹ Peptide binding studies suggested that two closely spaced clusters of basic amino acids at positions 149–155 and 159–166 may mediate binding to GAGs.⁵⁵¹

Deletion of G from recombinant HMPV was less attenuating than for HRSV. Deletion of G had little effect on HMPV replication *in vitro*, and the HMPV Δ G mutant had a low-to-moderate level of replication in hamsters and AGMs.^{44,48} Interestingly, infection of epithelial cells *in vitro* with the Δ G mutant resulted in increased activation of the transcription factors IRF3 and NF- κ B and increased expression of type I IFN and proinflammatory cytokines compared to wild-type HMPV, implying that the G protein otherwise inhibits these responses.²¹ The HMPV G protein was found to bind to the RIG-I cytoplasmic RNA recognition receptor, which explains its inhibitory effect.

Small Hydrophobic SH Protein

The HRSV SH protein (Fig. 38.4) is a short (64 amino acids for strain A2) transmembrane protein that is anchored by a hydrophobic signal-anchor sequence near the N-terminus, with the C-terminus oriented extracellularly.^{101,427} Most of the SH protein remains unglycosylated (Mr ~7,500), but there are also forms that contain a single N-linked side chain (resulting in Mr ~13,000 to 15,000), as well as the further addition of polylactosaminoglycan (Mr ~21,000 to 60,000 or more), as well as N-terminally truncated forms that arise from translational initiation at the second methionine codon in the ORF.^{9,427} However, the significance of these multiple forms is not known.

Chemical cross-linking studies indicated that the HRSV SH protein associates into pentamers.¹⁰¹ When SH was expressed in bacteria, it was incorporated into the membrane, resulting in increased membrane permeability.⁴⁴⁶ Incorporation of partial or full-length SH into artificial membranes *in vitro* resulted in the formation of pentameric and hexameric pore-like structures and the acquisition of cation-selective channel-like activity.^{81,183} Therefore, the SH protein may have properties of a viroporin, which typically are small proteins that modify membrane permeability and can have roles in budding and apoptosis.

Recombinant HRSV from which SH was deleted replicates with wild-type efficiency *in vitro* and appears to be fully fusogenic.^{69,544} The SH protein was reported to reduce apoptosis, but the effect was small.¹⁸¹ SH also appeared to inhibit signaling from tumor necrosis factor (TNF)- α .¹⁸¹ The Δ SH virus was slightly attenuated in mice and chimpanzees,^{69,603} but deletion of the SH gene in an experimental live vaccine strain did not increase its level of attenuation in seronegative children.²⁹⁰ Therefore, the function(s) and impact of the HRSV SH protein seem unclear.

The SH protein of HMPV is nearly three times longer (177–183 amino acids) than its HRSV counterpart^{46,571} (Fig. 38.4). It has the same membrane orientation and a similar array of nonglycosylated and glycosylated forms. Passage of HMPV frequently results in mutations that ablate SH expression,⁴³ suggesting that the protein may be somewhat toxic in cell culture. Infection of epithelial cells and mice with the Δ SH virus resulted in a modest increase in NF- κ B activation and expression of proinflammatory proteins compared to wild-type virus, suggesting that the SH protein downregulates the innate response, but the effect may be small.²⁰ *In vivo*, deletion of SH had little or no effect on HMPV replication in hamsters or in AGMs.^{44,48}

Matrix M Protein

The HRSV M protein is a nonglycosylated internal virion component that is smaller than its *Paramyxovirinae* counterparts (256 amino acids versus 335–375 amino acids), with little apparent amino acid sequence relatedness. HRSV M appears to play two roles typical for *Mononegavirales*: it helps organize virion components at the plasma membrane for budding,^{254,547} and it may silence viral RNA synthesis in preparation for packaging into the virus particle.¹⁹¹ A crystal structure determined for the HRSV M protein revealed a monomer that is organized into compact N-terminal (residues 1 to 126) and C-terminal (residues 140–255) domains joined by a 13-residue linker.³⁹⁴ The surface of M was found to contain a large positively charged area that extends across the two domains and the linker and may mediate association with the negatively charged membrane as well as with nucleocapsids.³⁹⁴ The HMPV M protein (254 amino acids) likely is a close functional counterpart.

Nucleocapsid/Polymerase Proteins N, P, L, and M2-1

The N, P, and L proteins of HRSV appear to be close functional analogs of their counterparts in other members of *Paramyxoviridae*. The N protein binds tightly along the entire length of genomic RNA and antigenomic RNA to form separate RNase-resistant nucleocapsids that are templates for RNA synthesis. The P protein is a multifunctional adapter that helps mediate interactions between components of the nucleocapsid/polymerase complex. The L protein contains the polymerase catalytic domains. Studies with HRSV minireplicons showed that N, P, and L are necessary and sufficient to direct RNA replication.^{98,215,626} N, P, and L alone also have transcriptase activity, but fully processive transcription requires in addition the M2-1 protein.^{98,171}

The 391 amino acid HRSV N protein is shorter than its counterparts in *Paramyxovirinae* (approximately 490–555 amino acids), and sequence relatedness is limited to several conserved segments located towards the C-terminus.^{27,542} HRSV N protein produced in bacteria was recovered in decamer rings bound to bacterial RNA, and a crystal structure was obtained⁵⁴² that is described in e-Figure 38.5.

The HRSV P protein (241 amino acids) is shorter than its *Paramyxovirinae* counterparts (approximately 390–605 amino acids) and lacks evident sequence relatedness. However, it is thought to have the same general array of functions. Like its counterparts in *Paramyxovirinae*, HRSV P operates as a stable homotetramer formed through a multimerization domain in the middle of the molecule.^{15,82,344} The C-terminal region of the P tetramer interacts with N protein in the nucleocapsid by binding to a hydrophobic pocket surrounded by positively charged

residues made up from discontinuous segments within amino acids 46–151 of the N protein, a structure distinct from that of other members of *Mononegavirales*^{182a} (e-Fig. 38.5). Soluble P also binds to free N protein monomers—probably through the N-terminal domain of P—and delivers N to nascent genomes/antigenomes during RNA replication. P thus prevents N from self-aggregating or binding to nonviral RNA.⁸² In addition, P binds to the L²⁹⁴ and M2-1^{12,559} proteins and helps mediate their interactions with the nucleocapsid. P is an essential polymerase co-factor. It may contribute to conformational changes that help the polymerase access the RNA template⁸² and appears to be necessary for promoter clearance and chain elongation by the viral polymerase.¹⁴⁷ It also appears to have a role in dissociating the M protein from the nucleocapsid during uncoating to initiate infection.¹³

P is the major phosphorylated HRSV protein and contains phosphate 10 to 12 or more sites, with different sites exhibiting differing rates of turnover: the C-terminal domain contains low-turnover phosphates and accounts for most of the total phosphate, the middle domain contains intermediate-turnover phosphates, and the N-terminal domain contains high-turnover phosphates.^{14,418} Many of the activities of P described above appear to be directed by dynamic phosphorylation and dephosphorylation of P at a subset of these sites, usually involving a small percentage of the total phosphate content.^{12,13,14–15,580} Most of the constitutive phosphorylation, involving five sites, could be ablated in recombinant HRSV with only modest effects on virus growth.³⁵⁰

The 194 amino acid HRSV M2-1 protein is an essential transcription processivity factor; in its absence, the viral polymerase terminates prematurely and nonspecifically within several hundred nucleotides of the 3' end of the genome, and downstream genes are not significantly transcribed.^{94,97,98,171} M2-1 also decreases the efficiency of termination at the GE transcription signals—possibly a reflection of the same processivity activity—resulting in increased production of readthrough mRNAs.²⁴⁵ HRSV M2-1 accumulates in phosphorylated and nonphosphorylated forms²⁴⁴ and forms a homotetramer via an oligomerization domain at residues 32 to 63.⁵⁵⁹ M2-1 contains a cysteine–histidine zinc finger motif (C-X₇-C-X₅-C-X₃-H) near its N-terminus (residues 7 to 25) that is essential for its activity²⁴⁴; this motif is conserved in *Pneumovirinae*.⁵⁷¹ The HRSV M2-1 protein binds RNA, and may be delivered to the RNA template by the P protein.^{80,120,559} M2-1 is unique to *Pneumovirinae*, although VP30 of Family *Filoviridae* has some similarities.

The 2,165 amino acid HRSV L protein is similar in length to its *Paramyxovirinae* counterparts and has low but unambiguous sequence relatedness along nearly its entire length.⁵²⁷ Specific segments of L are conserved within and beyond *Mononegavirales* and appear to include polymerase motifs.⁴⁵¹ A putative nucleotide-binding domain involved in capping mRNA was identified in the central region of the L protein based on sequence analysis of HRSV mutants selected for resistance to novel capping inhibitors, in which resistance was associated with an amino acid substitution at position 1381, 1269, or 1421.³⁴³ In separate work, an amino acid substitution at position 1049 or 1169 in the L protein was associated with reduced efficiency of termination at the GE signals, resulting in increased synthesis of polycistronic mRNAs and reduced growth efficiency.^{79,282}

The HMPV N, P, L, and M2-1 proteins are similar in size to their HRSV counterparts and share significant amino acid

sequence identity^{46,571} (Table 38.1). One notable difference is that, whereas M2-1 appears to be essential for HRSV, recombinant HMPV in which the M2-1 ORF has been silenced is viable and replicates *in vitro* with an efficiency that is only marginally reduced.⁶⁶ HMPV lacking M2-1 appeared to execute processive transcription efficiently, although the level of RNA accumulation was somewhat reduced. Therefore, in contrast to HRSV, HMPV M2-1 appears to be a nonessential accessory protein of unknown function.⁶⁶ However, in the hamster model, replication of HMPV lacking M2-1 could not be detected, indicating that M2-1 is important for replication *in vivo*.

M2-2 Protein

HRSV M2-2 is a small (90 amino acids for strain A2) protein that is expressed at a low level that may reflect inefficiency of the stop–restart mechanism of translation noted previously.⁵ It is not known whether M2-2 is packaged in the virion. Recombinant HRSV in which the M2-2 ORF has been silenced grows more slowly *in vitro* than wild-type HRSV, although it eventually achieves a similar titer.^{41,271} In Δ M2-2 virus–infected cells, the accumulation of mRNA was increased, whereas that of the genome and antigenome was decreased compared to wild-type virus. Conversely, when M2-2 was overexpressed during HRSV infection—using a co-transfected plasmid or a recombinant HRSV in which expression of M2-2 was upregulated by engineering it to be a separate gene⁸⁹—HRSV replication was inhibited. Expression of M2-2 also was inhibitory to HRSV RNA synthesis by a minireplicon.⁹⁸ These observations indicate that M2-2 plays a role in shifting RNA synthesis from transcription to RNA replication, that M2-2 can be inhibitory to RNA synthesis, and that the inhibitory activity occurs with increased M2-2 expression. The Δ M2-2 virus retained the ability to replicate in mice and chimpanzees, but it was attenuated approximately 500- to 1,000-fold compared to wild-type HRSV.^{41,271,549}

HMPV encodes a 71 amino acid M2-2 protein from a comparable internal ORF in its M2 mRNA^{46,571} (Fig. 38.3C). The HMPV M2-2 protein co-immunoprecipitated with the L protein and inhibited RNA synthesis by a mini-replicon, an activity that was lost by short deletions at the N- or C-terminus of M2-2.³⁰¹ Deletion of HMPV M2-2 from recombinant virus resulted in an attenuated virus in which transcription is increased and RNA replication decreased.⁶⁶

Nonstructural Proteins NS1 and NS2

The NS1 and NS2 proteins (139 and 124 amino acids, respectively) are unique to the genus *Pneumovirus*. NS1 and NS2 can be co-immunoprecipitated⁵³⁷ and may occur in complexes of various stoichiometries.¹⁵⁶ Monomeric NS2 was unstable with a half-life of 30 minutes.¹⁵⁶

NS1 and NS2 strongly interfere with the induction and signaling of type I IFN and type III IFN (the latter comprising λ 1, λ 2, and λ 3; also known as IL-29, IL-28A, and IL-28B, respectively) in human epithelial cells, macrophages, and dendritic cells. This suppresses a major component of host innate defense. The steps at which NS1 and NS2 act are summarized in e-Figure 38.6.

Deletion of NS2 from recombinant HRSV decreased its ability to induce activation of transcription factor NF- κ B,⁵²⁴ and small interfering RNA (siRNA)–mediated knockdown of the expression of either NS1 or NS2 in HRSV-infected cells

reduced activation of NF- κ B and the serine-threonine kinase AKT (also known as protein kinase B), with the effect of speeding the onset of apoptosis.⁵⁰ Therefore, the two NS proteins appear to activate prosurvival pathways, thereby prolonging the life of the cell and increasing the viral yield.⁵⁰

In a minireplicon system, coexpression of NS1—and, to a lesser extent, NS2—inhibited transcription and RNA replication, affecting both the genomic and antigenomic promoters.¹⁶ These effects remain to be defined. The V and C accessory proteins of some members of *Paramyxovirinae* also have been shown to downregulate viral RNA synthesis (Chapters 33 and 34). This may be a general viral mechanism to prevent excessive RNA synthesis and avoid the accumulation of naked genomic/antigenomic RNA and the formation of dsRNA, which otherwise would activate the RIG-I/MDA5/PKR pattern recognition molecules.

As might be expected from the results described above, HRSV lacking NS1 and/or NS2 replicates to reduced titer in cultured cells competent for producing type I IFN, as well as in experimental animals, with the level of attenuation increasing in the order Δ NS2 < Δ NS1 \leq Δ NS1 + NS2.^{272,523,546,549,603}

Replicative Cycle

Efficient infection of cell lines *in vitro* by HRSV involves binding to cellular GAGs, especially heparan sulfate and chondroitin sulfate B.²³⁸ The G and F proteins each appear able to bind to GAGs.^{174,175,239,545} A number of additional potential receptor molecules for HRSV have been tentatively identified, including intracellular adhesion molecule (ICAM)-1,³³ RhoA,⁴³⁸ the CX3CR1 fractalkine receptor,⁵⁶¹ and annexin II.³⁵⁸ More recently, efficient HRSV infection *in vitro* and in the mouse model was shown to depend on binding to the cellular protein nucleolin,⁵⁴³ which also has been identified as a co-receptor for human parainfluenza virus 3 (HPIV3).⁵⁸ Somewhat unexpectedly, binding to nucleolin is mediated by the F protein rather than by the G protein. This suggests that efficient attachment and infection by HRSV depends on two different binding events mediated by G and F, but the details of this process remain unclear.

HRSV entry occurs by fusion of the viral envelope with the cell plasma membrane^{283,526} or with endosomal membranes following clathrin-mediated endocytosis.³⁰⁴ However, HRSV entry does not require endosomal acidification, suggesting that there is no mechanistic difference between entry at the plasma versus endosomal membrane.^{304,526} When infection was monitored by video microscopy, the initiation of fusion by attached virions appeared to be a slow step, but once started the process was rapid.¹⁸ Genome transcription and replication occur in the cytoplasm and the virus can grow in enucleated cells and in the presence of actinomycin D, indicating a lack of essential nuclear involvement.

HRSV mRNAs and proteins can be detected intracellularly at 4 to 6 h after infection and reach a peak accumulation by 15 to 20 hours. The release of progeny virus begins by 10 to 12 h postinfection, reaches a peak after 24 hours, and continues until the cells deteriorate by 30 to 48 hours. Transcription and RNA replication occur concurrently but, as noted, the low-abundance M2-2 protein accumulates during infection and shifts the balance of RNA synthesis from transcription to RNA replication.⁴¹ In minireplicon experiments, increasing the level of accumulation of the N and P proteins did not shift the balance between RNA replication and transcription, indicating

that the availability of protein to encapsidate replicative RNA does not control this balance.¹⁷²

Several factors influence the relative levels of expression of the various HRSV genes. Like other *Mononegavirales*, sequential transcription has a polar gradient due to polymerase fall-off, and thus promoter-proximal genes are expressed more efficiently. This gradient of expression is not very steep, with the exception of the L mRNA.^{107,307} The greatly reduced accumulation of L mRNA compared to the other mRNAs appears to be due to a posttranscriptional effect rather than polymerase fall-off, with one possibility being mRNA stability.³¹⁸ Differences in the termination efficiency of the various GE signals may also have effects on the relative levels of gene expression.^{246,399} For example, if a GE signal is particularly inefficient, a greater fraction of the polymerase continues synthesis into the next downstream gene to produce a readthrough transcript, rather than terminating and reinitiating to produce an individual transcript of the next gene. Because ORFs in internal positions in eukaryotic mRNAs generally are not efficiently translated,³⁰⁶ this would have the effect of down-regulating expression of the protein from the downstream gene. HMPV in particular has considerable variation in the efficiency of its GE signals, and in particular this appears to sharply down-regulate the production of monocistronic SH mRNA, contributing to the observed low level of expression of SH protein.

HRSV assembly and budding occur at the plasma membrane. In polarized cells, this occurs at the apical surface.^{475,631} Video microscopy showed that budding occurs within circumscribed regions on the cell surface and appeared visually to be the reverse of fusion.¹⁸ These regions contain localized virus-modified lipid rafts involving all three viral surface proteins and the M protein.^{254,270,371,372,623} The minimum viral protein requirements for the formation of virus-like particles capable of delivering the viral genome to target cells are the F, M, N, and P proteins,⁵⁴⁷ and expression of these proteins induced the formation of viral filaments.⁵⁶⁴

As has been observed for other members of *Paramyxoviridae*, HRSV utilizes the host cytoskeleton in its replicative cycle. Viral substructures are associated with polymerized actin throughout the infectious cycle.²⁶⁹ Actin is packaged in the virion and was required, in combination with profilin (an actin-binding protein involved in restructuring actin polymers), for efficient RNA synthesis by intracellular nucleocapsids in a cell-free reaction.⁷² HRSV appears to hijack cellular apical recycling endosomes (ACEs) for budding, a pathway that is distinct from that described for a number of other enveloped RNA viruses.^{65,564}

Efficient infection by HMPV *in vitro* depends on binding to cell surface GAGs and $\alpha\beta 1$ integrin.^{118,551} The F proteins of some strains of HMPV depend on acidification for activation, indicating a dependence on endosomal uptake rather than fusion at the plasma membrane: this requirement mapped to the presence of glycine at position 294.^{260,496,497} However, this was observed for only 6% of subgroup A strains and not for subgroup B, indicating an unexpected diversity in entry mechanisms. Finally, one notable difference between HRSV and HMPV is that the kinetics of infection of the latter in cell culture are slower, with the peak of intracellular protein expression occurring at 48 to 72 hours postinfection.

Propagation In Vitro

HRSV replicates most efficiently *in vitro* in immortalized cell lines derived from human epithelial cells, but can infect and replicate

to a significant extent in a wide variety of cell lines representing various tissues from various hosts, including humans, monkeys, bovines, hamsters, and mice. The most commonly used cell line is human HEP-2, now thought to have been contaminated historically with, and outgrown by, the HeLa cell line.³⁶⁸ Virus is usually quantified by plaque titration; immunostaining is often used to enhance visualization of plaques. Fresh clinical isolates of HRSV may undergo some sort of adaptation to cell culture,³⁶¹ but this is poorly understood. However, passaged laboratory strains retain their virulence for chimpanzees and humans.^{291,606}

In cell culture, 90% of progeny HRSV virions remain associated with the cells, attached in a manner that suggests a failure to complete the budding process. To make virus stocks, cell-associated virus is dislodged by freeze-thawing, sonication, or vortexing. The yield is low, typically ten plaque-forming units (pfu) per cell. Virion preparations commonly have substantial contamination by cellular debris. A large fraction of released virions appeared to be empty and presumably noninfectious.¹⁹ Less than 5% of the infectivity of a preparation of HRSV passed through a 0.45- μ m filter, whereas more than 85% passed through a 3- μ m filter, consistent with the infectious particles being filaments⁴⁷⁵; similar findings had been reported for BRSV.⁴³³

HMPV is more restricted in its *in vitro* host range than HRSV, but is readily propagated in rhesus LLC-MK2 or AGM Vero cells.^{134,557} HMPV typically requires added trypsin to support cleavage of the F protein, although some strains mutate during passage to become trypsin independent, as noted.⁴⁹² HMPV replicates more slowly than HRSV, its cytopathic effect is less prominent, and the yield of infectious virus is similarly low. Like HRSV, HMPV tends to remain cell-associated but is more stable.

Genetics and Reverse Genetics

HRSV (and presumably HMPV) has a high rate of nucleotide substitution, as is typical for RNA viruses. The rate of nucleotide substitution in RSV was estimated to be 6.47×10^{-4} substitutions/site/year, and the G gene had the elevated rate of $10^{-2.7}$ substitutions/site/year, reflecting relaxed selective constraints, as already noted.^{538a,641} HRSV and HMPV, like other *Mononegavirales*, also engage in nonhomologous recombination caused when the polymerase jumps from one template to another during synthesis. This can create defective interfering (DI) genomes,⁵⁶⁹ or deletion of parts of genes,²⁸⁸ or sequence duplications.⁵⁶⁰ Foreign sequence also can be acquired, as evidenced by a 1,015-nucleotide insert of unknown origin in the G gene of certain AMPV-C isolates.³⁸ Recombination between co-infecting viruses appears to be rare, although potential mosaic genomes within a viral species are identified occasionally by sequence analysis.⁶³⁴ One study detected a single case of recombination between two co-infecting HRSV mutants in cell culture, involving both homologous (i.e., guided by sequence relatedness) and non-homologous recombination⁵²²; this is the only such report for *Mononegavirales*. In addition, the difference in the gene orders of HRSV and HMPV may be evidence of past recombination, within one or the other species, resulting in gene rearrangement.

As with other *Mononegavirales*, HRSV and HMPV can be produced entirely from cloned cDNA by reverse genetics, involving co-transfection of plasmids encoding a copy of the genome or antigenome as well as the proteins of the nucleocapsid/polymerase complex. The viral protein requirements for recovering HRSV are N, P, L, and M2-1, but M2-1 is not

required for HMPV.^{47,66,97,259} A second type of reverse genetics system that has been used extensively for HRSV in particular is based on cDNA-encoded minireplicons in which the viral genes in the genome or antigenome cDNA have been replaced by one or more foreign marker genes, with the system driven by viral proteins supplied from co-transfecting plasmids. Depending on the supplied proteins, this system can recreate genome encapsidation, transcription, RNA replication, and particle morphogenesis.^{98,170,373,424,547} This system is ideal for detailed structure-function studies. In addition, mutations that might have drastic or lethal effects on infectious virus can readily be studied in the transient context.

Infection of Experimental Animals

A number of animal species can be infected in the respiratory tract by intranasal administration of HRSV, including cotton rats, mice, ferrets, guinea pigs, hamsters, marmosets, lambs, and various nonhuman primates.^{35,73,210,460,521,606} Among experimental animals, only the chimpanzee approaches the human in being highly susceptible to infection by contact, in supporting moderate to high levels of virus replication, and in exhibiting rhinorrhea and cough resembling that of humans. The most widely used experimental animals, cotton rats and mice, support a low to moderate level of virus replication that peaks on day 4 and is cleared quickly. *In situ* hybridization of lung tissue from cotton rats at the peak of virus replication showed that only scattered cells were infected.⁴¹³ Inbred strains of mice can vary 100-fold in permissiveness for replication.⁴⁶⁰ The BALB/c mouse is one of the more permissive strains, but it is less permissive than cotton rats. Rodents do not exhibit overt HRSV respiratory tract disease, although pulmonary histopathologic changes are evident and disease can be monitored by weight loss and changes in pulmonary function. More recently, newborn lambs have been used as models in detailed studies of neonatal HRSV disease.⁵²¹

Intranasal administration of HMPV has been reported to infect guinea pigs, ferrets, mice, cotton rats, and hamsters, and several species of nonhuman primates.^{6,241,353} BALB/c mice and hamsters may be more permissive for HMPV than for HRSV. Among nonhuman primates, cynomolgus macaques and AGMs support moderate levels of virus replication that peak on days 5 to 6 and are mostly resolved by day 10.^{311,515} Captive cynomolgus macaques, AGMs, and chimpanzees have a high seroprevalence for HMPV, suggesting that they can be infected readily from their handlers and possibly by animal-to-animal transmission.

Antigenic Subgroups and Diversity

HRSV has a single serotype with two antigenic subgroups, A and B. These exhibit a three- to fourfold reciprocal difference in neutralization by polyclonal convalescent serum.⁹² Studies with MAbs have demonstrated extensive antigenic difference in the G protein with substantially less difference in the other viral proteins.^{10,400} Analysis of glycoprotein-specific responses in cotton rats or human infants by enzyme-linked immunosorbent assay (ELISA) with purified F and G glycoproteins (the HRSV neutralization antigens) showed that F has 50% antigenic relatedness between subgroups compared to 1% to 7% relatedness for G.²⁵⁶ Consistent with this, F protein expressed from a recombinant vaccinia virus was equally protective in cotton rats against infection with either subgroup, whereas the

G protein was 13-fold less effective against the heterologous subgroup virus.²⁷⁷ Therefore, the F protein is responsible for most of the observed HRSV cross-subgroup neutralization and protection.

The genomes of the two HRSV subgroups share 81% nucleotide identity. The various proteins vary considerably in their level of subgroup divergence, with M2-2, SH, and G being the most divergent (Table 38.1). The divergence is greatest for the ectodomains of SH and G, which exhibit only 50% and 44% sequence identity between subgroups, respectively.^{105,278} The genome-wide nature of the sequence differences indicates that the two subgroups represent two lines of divergent evolution, rather than being variants that differ only at a few major antigenic sites. The divergence of the two HRSV subgroups has been estimated to have occurred approximately 350 years ago.⁶⁴⁰ In addition, there is considerable variation within each subgroup: for example, the G glycoprotein can have 20% difference between strains from the same subgroup.

The HRSV F protein is relatively stable antigenically, consistent with its high level of sequence conservation between the two HRSV subgroups. For example, analysis of 18 subgroup A strains and five subgroup B strains recovered from geographically diverse regions over 30 years using F-specific murine MAbs representing 16 separate neutralization epitopes in four antigenic sites showed that seven epitopes were conserved in all but one of the strains.³² Similarly, a major epitope in the N protein for CD8⁺ cytotoxic T lymphocytes (CTLs) was highly conserved in field strains.⁵⁷⁸

The G protein appears to be subject to greater change, although this occurs incrementally over a period of years. In one study, analysis of HRSV isolates collected over 47 years suggested that positive selection occurred at 13 codons in the G ectodomain, a number of which involved known epitopes.⁶⁴¹ A second study of isolates collected over 38 years provided evidence of progressive amino acid changes at an average rate of 0.25% per year that were paralleled by changes in reactivity with MAbs.⁷⁶ The mucin-like domains in G are unusual in that they are more divergent at the amino acid level than at the nucleotide level,²⁷⁸ which is the converse of what is observed for most proteins. This suggests that there is a selective pressure for amino acid substitutions, presumably driven by immune pressure. These regions in G may be relatively tolerant of amino acid change because of their proposed extended, nonglobular structure. In contrast, although F would be subjected to the same selective immune pressure, it likely is less tolerant of amino acid substitutions due to constraints from its folded structure and functional requirements. Analysis of BRSV isolates, including those from countries in which vaccination was in wide use, provided evidence of modest progressive changes not only in G, but also in N and F.⁵⁶⁸

HMPV also has a single serotype with two antigenic subgroups, A and B, which have extensive cross-reactivity and cross-protection.^{55,259,442,572,574} The level of genome nucleotide sequence identity (80%) and the relatedness between the various proteins is similar to that described for HRSV (Table 38.1). The HMPV F protein is somewhat more conserved than that of HRSV and plays a major role in the high level of cross-neutralization and protection between the two subgroups.⁵¹⁵ Vaccination against AMPV appears to drive antigenic drift in the field, especially in the G and SH genes, resulting in virus

that is sufficiently divergent from the vaccine strain that it is less restricted by vaccination.⁸⁴

Animal Counterparts

The BRSV gene map is very similar to that of HRSV.^{67,627} The genome of BRSV strain A51908 (NC_001989 and AF295543) contains 15,140 nucleotides and has 73% nucleotide identity with HRSV. Amino acid sequence identity ranges from 30% (G protein) to 93% (N protein) (Table 38.1), and there is extensive antigenic cross-reactivity. BRSV and HRSV have broadly overlapping host ranges in cell culture; however, *in vivo*, BRSV is highly restricted in nonhuman primates.⁶⁸ Ovine and caprine RSV also have been described. Sequence analysis suggests that ovine RSV and BRSV represent two branches of ruminant RSV with a degree of divergence similar to that between the HRSV antigenic subgroups. Caprine RSV appears to be more closely related to BRSV than to ovine RSV.¹¹²

PVM was first identified during experiments in which clinical material was passaged in mice in an effort to identify new human pathogens, and an apparent mouse virus present in the animals became evident.²⁶⁴ PVM is a respiratory pathogen that readily infects mice and other rodents and can be highly virulent. However, the natural host of PVM is unclear: the virus occasionally appears in colonies of laboratory mice, but serologic studies usually find little evidence of PVM-specific antibodies in wild rodents under conditions where there is extensive seropositivity for other common rodent viruses.^{31,516} Serologic studies suggested that a substantial proportion of the human population has antibodies that react with PVM.⁴⁶⁴ However, further analysis suggested that infection of humans by PVM or a closely related virus is unlikely.^{64a} A virus that was recently isolated from dogs with acute respiratory disease appears to be a strain of PVM (e.g., the percent amino acid sequence identity between the isolate and PVM strain 15 ranged from a low of 90.2% [SH] to a high of 98.1% [M]).^{473,474} Whether PVM commonly infects and causes respiratory tract disease in dogs remains unknown. The PVM gene map³⁰⁸ is essentially the same as that of HRSV and BRSV except that (a) the M2 and L genes of PVM do not overlap, and (b) the PVM P gene contains a second ORF that encodes a 137-amino acid product that represents a novel, 12th PVM protein.²⁶ The complete nucleotide sequence of PVM strain 15 (AY729016) is 14,886 nucleotides in length and has 52% identity with that of HRSV.³⁰⁸ The level of amino acid sequence identity ranges from 10% (M2-2 protein) to 60% (N protein) (Table 38.1).

BRSV and PVM in their respective hosts are used as models for HRSV,^{190,285,441,481,614} although a review of these studies is beyond the scope of this chapter. The BRSV model is limited by the inconvenient nature of the large host. PVM differs from HRSV in that lethal infections are typical rather than an infrequent outcome, but it can serve as a model for severe pneumovirus disease and has the advantage of the many available murine immunologic reagents and inbred mouse strains.

AMPV causes respiratory tract disease of economic importance in turkeys and also infects chickens and other birds.⁴²¹ Four AMPV antigenic subgroups have been described: subgroups A and B have been found in South Africa, Europe, Israel and Asia; subgroup C in North America; and subgroup D in France.⁴²¹ Complete genomic sequences have been determined for strains of subgroup A (AY640317) and subgroup C (AY590688 and AY579780). These range in length from 13,134 to 14,150 nucle-

otides, have the same general gene map as HMPV, and share 61% to 68% nucleotide sequence identity with HMPV subgroup A. Subgroups A, B, and D are more closely related to each other than to C^{205,504} (e-Fig. 38.2B). Surprisingly, AMPV-C is more closely related to HMPV than to the other AMPV subgroups^{571,572} (e-Fig. 38.2B). Sequence analysis of isolates collected over a 25-year period suggested that the most recent common ancestor for AMPV-C and HMPV existed approximately 200 years ago, implying a cross-species jump.¹²⁷ There is substantial host range restriction between human and avian MPV. AMPV-C (the subgroup most closely related to HMPV) is highly restricted in nonhuman primates.⁴⁴⁷ HMPV has been reported to be unable to infect chickens and turkeys,⁵⁷² or to transiently infect turkeys.⁵⁷⁷

PATHOGENESIS AND PATHOLOGY

In typical monolayer cultures of immortalized cells, infection with HRSV or HMPV results in long surface filaments that bear viral antigen and probably give rise to filamentous virus particles⁴⁸⁹ (Fig. 38.2B and E). The formation of HRSV filaments and filamentous virus depends on activation of RhoA and actin rearrangement: when activation is blocked, the production of infectious virus shifted to the nonfilamentous form.^{71,206,371} HRSV-infected cells develop large electron-dense cytoplasmic inclusion bodies of up to several microns in diameter that include the N, P, M2-1, and L proteins and presumably contain active nucleocapsids^{78,185}; HMPV forms similar inclusions.¹³⁶ Recently, the HRSV inclusion bodies were found to sequester a number of cellular proteins involved in intracellular signaling pathways, with the effect of inhibiting innate immunity and stress responses.^{179a} HRSV infection has slight inhibitory effects on cellular DNA and RNA synthesis and little effect on gross protein synthesis.³³⁵ As one factor in the lack of inhibition of protein synthesis, the HRSV N protein binds to PKR and prevents it from phosphorylating eIF-2 α and inhibiting protein synthesis.²¹⁶ Apoptosis of HRSV-infected cells occurs slowly and is inhibited by the NS1, NS2, and SH proteins, as already noted. HRSV blocks the formation of stress granules, which may otherwise restrict HRSV replication.^{179a, 242} The formation of syncytia (Fig. 38.2A) is a major factor in cell death in typical nonpolarized monolayer cell cultures, but usually is not a prominent histopathologic finding *in vivo* (below).

HRSV and HMPV are highly infectious viruses. Humans are their only natural host, although HRSV and HMPV can readily spread to nonhuman primates and are pathogenic in some situations.³⁰⁵ The major mode of spread by HRSV is by large droplets or through contaminated objects and depends on close contact with infected individuals or contact of contaminated hands to nasal or conjunctival mucosa (self-inoculation). It is generally thought that small-particle aerosols (which can remain airborne for extended periods and also can be inhaled deeply into the respiratory tract) are not an important mode of HRSV transmission,^{222,224} although there are contrary data.³³⁸ The incubation period from time of infection to onset of illness for HRSV is about 3 to 5 days^{137,286,291} (Fig. 38.5). The incubation period for HMPV is not defined, but is thought to be similar.

HRSV replicates initially in the nasopharynx. Signs of LRI, when it occurs, usually appear 1 to 3 days following the onset of rhinorrhea (Fig. 38.5). Viral spread to the lower respiratory tract likely involves aspiration of secretions. Infants hospitalized

FIGURE 38.5. Time course of viral shedding and disease signs following experimental infection of a young seronegative vaccinee with 10^4 pfu of an investigational live partially attenuated human respiratory syncytial virus (HRSV) vaccine called *cpts248/955*. Fever was intermittent. (Adapted from Karron RA, Wright PF, Crowe JE, Jr, Clements ML, et al. Evaluation of two live, cold-passaged, temperature-sensitive respiratory syncytial virus (RSV) vaccines in chimpanzees, adults, infants and children. *J Infect Dis* 1997;176:1428–1436.)

for HRSV disease shed infectious virus in nasal secretions with peak titers of 10^4 to 10^6 infectious units per ml.^{138,139,225,615} Many infants continue to shed virus at hospital discharge and a few can continue to shed virus for weeks following clinical recovery. With the use of quantitative reverse transcription polymerase chain reaction (RT-PCR), the period of detection of HRSV shedding is prolonged, suggesting that virus is present but is neutralized by secretory antibodies made in response to the infection.^{137,351} Limited data suggest that the titer of virus in the lower respiratory tract, sampled in bronchoalveolar lavage fluids of ventilated patients, is similar to that in the upper respiratory tract. Infectious virus has been difficult to recover from adults during symptomatic infection despite positive serologic or RT-PCR tests, probably due to the presence of neutralizing antibodies.

HRSV principally exhibits tropism for the airways and lung tissues. Studies in human adenoid or HAE epithelium models *in vitro* showed that HRSV preferentially infected cili-

ated cells. Infection was limited to the apical surface and did not spread to underlying cells, and virus was released from the apical surface^{562,616,631} (Fig. 38.6). In experimental HAE infections lasting several weeks, infected cells were shed and replaced with little visible alteration of the microscopic appearance of the tissue, although ciliary beating usually was impaired.^{616,631} Syncytia were not observed, probably because the F glycoprotein was expressed on the apical surface and did not contact adjacent cells. HRSV contrasted sharply with influenza A virus examined in parallel, which was rapidly destructive and quickly spread to underlying cells.^{616,631} HRSV infection of epithelial cells induces a rapid inhibition of Na^+ transport, resulting in apical fluid accumulation.³¹⁴ This might be a host mechanism to dilute and remove irritants, but also might contribute to excess fluid and virus spread. This effect was not unique to HRSV, and was observed with parainfluenza and influenza viruses as well as with bacterial pathogens.

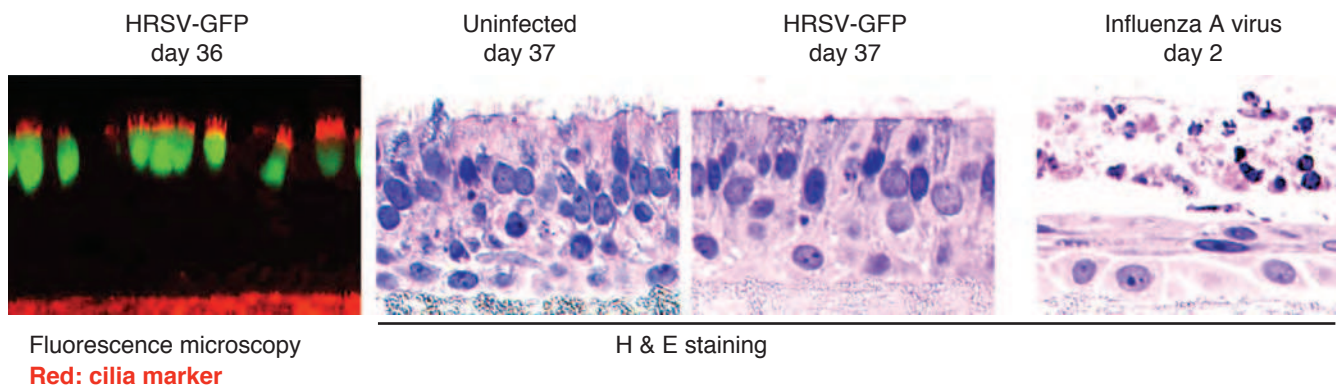

FIGURE 38.6. Infection of an *in vitro* model of human airway epithelium (HAE) with human respiratory syncytial virus (HRSV) and influenza A virus, shown in cross-section. The left hand panel is a fluorescence photomicrograph of cells 36 days following infection with HRSV expressing green fluorescent protein (GFP), and also stained with antibody specific to cilia (*red*; note that this antibody also stained the filter support underlying the cells). The three panels to the right show mock-infected, HRSV-infected, and influenza A virus-infected cultures visualized 37 (mock and HRSV) or 2 (influenza) days postinoculation.⁶³¹ In the three right-hand panels, the cells were stained with hematoxylin and eosin.

FIGURE 38.7. Histopathology of human respiratory syncytial virus (HRSV) infection in children. **A:** Bronchiolar localization of HRSV antigen (stained brown) detected by immunohistochemistry. (1) HRSV antigen localized in the luminal epithelium of two bronchioles (arrows indicate examples of staining). (2) Higher magnification of infected ciliated cells of the luminal surface of the bronchiole (an example is indicated with the arrow), also showing that the basal progenitor cells (an example is circled) are not infected. (3) Intraluminal debris (the arrow indicates a large debris plug) in a small airway, staining positively for HRSV antigen (an arteriole is marked with "a"). (4) A small syncytium (arrow). **B (left):** Alveolar localization of HRSV antigen (brown) detected by immunohistochemistry. (1) HRSV-infected alveolar cells (the arrow indicates an infected cell). (2) Alveolar lumens and small airways clogged with debris (examples are indicated with the arrows) that stains positively for HRSV antigen. **C (right):** Histopathologic features of bronchiolar inflammation, with periodic acid-Schiff (PAS) staining of carbohydrate macromolecules. (1) Bronchiole occluded with an intraluminal plug of debris and inflammatory cells (arrow). (2) Higher magnification image of intraluminal debris. (Reprinted by permission from Macmillan Publishers Ltd. From Johnson JE, Gonzales RA, Olson SJ, et al. The histopathology of fatal untreated human respiratory syncytial virus infection. *Mod Pathol* 2007;20:108–119; copyright 2007.)

Histopathology of fatal HRSV infections indicates that infection is limited to the superficial cells of the respiratory tract, consistent with the findings in HAE cultures, although it is likely that nonciliated cells also are infected^{4,187,273,596} (Fig. 38.7). There is necrosis and destruction of ciliated cells and occasional proliferation of the bronchiolar epithelium, but basal cells are spared. Ciliated epithelial cells rarely reappear before 2 weeks postinfection, and complete restoration requires 4 to 8 weeks,²²⁰ similar to the duration of postinfection altered lung function and airway reactivity in adults.²³⁷ There is an early influx of polymorphonuclear cells, and a peribronchiolar infiltrate of lymphocytes, plasma cells, and macrophages develops, with migration of the lymphocytes among the mucosal epithelial cells. Submucosal and adventitial tissues become edematous, and secretion of mucus is excessive, which combines with cell debris and inflammatory cells to obstruct the bronchioles and alveoli, causing either collapse or emphysema of distal portions of the airway. HRSV infects both type I and type II alveolar cells.²⁷³ In those instances in which pneumonia occurs, the interalveolar walls thicken as a result of mononuclear cell infiltration, and the alveolar spaces may fill with fluid. There is usually a patchy appearance of these pathologic changes, even though disease may be widespread. Immunostaining identified virus-infected cells in the bronchial, bronchiolar, and alveolar epithelium.^{273,419} Syncytia are sometimes observed, but are not prominent. However, syncytium formation and giant cell pneumonia are hallmarks of infection in individuals with extreme T-cell deficiency. HRSV antigen can be relatively abundant in lower respiratory tract infection, although the staining is usually focal, and in some cases of fatal HRSV bronchiolitis, antigen was present only in small amounts.^{187,419} The histopathology of HMPV infection is not well known but has been reported to involve a characteristic enlarged, darkly staining pneumocyte or “smudge cell” that is not seen with other respiratory paramyxoviruses.⁵³² Studies in nonhuman primates indicate that HMPV has a similar tropism for the superficial cells of the respiratory epithelium.³¹¹

Infection by HRSV and HMPV is largely limited to the respiratory tract. Infectious virus has not been recovered from the blood of HRSV- or HMPV-infected humans. However, viral nucleic acid can frequently be detected in the blood of HRSV-infected infants,⁴⁷⁸ and there are isolated reports of HRSV RNA in cerebrospinal fluid and myocardium.¹⁴⁹ HRSV antigen has been detected in circulating mononuclear leukocytes.¹⁴³ HRSV, HMPV, and influenza viral RNA have been detected in sera of immunosuppressed individuals infected with the respective viruses with high viral loads in the respiratory tract.⁷⁵ When immunosuppressed cotton rats are infected with HRSV, infectious virus was cultured from the liver and kidneys in a small proportion of animals.²⁷⁹ HRSV has been cultured from the myocardium of an infected infant with combined immunodeficiency as well as from a liver biopsy from an infected immunocompetent infant.^{149,178} This suggests that HRSV (and these other respiratory viruses) has some potential to spread beyond the respiratory tract, but usually is restricted by host immunity. A possible role in extrapulmonary disease manifestations has been suggested.¹⁴⁹

HRSV is not thought to cause a latent or persistent infection, and the virus is rarely recovered in the absence of respiratory disease. However, some reports suggest the prolonged persistence of virus or viral material. Infectious virus has been recovered

from guinea pigs 60 to 100 days postinfection,¹²⁴ and was recovered sporadically from mice 100 days postinfection upon T-cell depletion.⁴⁹⁹ BRSV RNA and proteins have been detected in bovine pulmonary lymph nodes 71 days following infection, and there was indirect evidence for *in vitro* infectivity from isolated bovine B lymphocytes.⁵⁶⁵ There is conflicting evidence as to whether HRSV might persist in some individuals with stable chronic obstructive pulmonary disease.^{161,511} HRSV was shed for 199 days, largely without disease, in a child infected with human immunodeficiency virus (HIV),²⁹⁹ and persistent symptomless shedding of HMPV has been described in a number of hematopoietic stem cell transplant (HSCT) recipients.¹³³

The available information suggests that there are not marked differences in replication or virulence among HRSV isolates. Some reports have suggested that subgroup A, or a particular genotype of subgroup A, is associated with increased replication and virulence, but a number of studies have not found such a link.^{63,251,363,518} Recently, an HRSV strain called line 19 was shown to induce increased lung IL-13 expression and mucous secretion in BALB/c mice, an effect that mapped to the F gene,³⁹⁵ raising the possibility that clinically relevant heterogeneity in strain virulence may be uncovered by further investigation. With HMPV, there presently is no indication that specific genotypes are associated with increased disease.^{1,60}

Primary HRSV disease is usually symptomatic, but disease manifestations can vary greatly, and may include upper respiratory tract illness (URI), fever, otitis media, LRI ranging from mild disease to bronchiolitis and/or pneumonia with or without subsequent long-term abnormalities in pulmonary function (see *Clinical Features*), and death in rare cases. Infection in immunosuppressed individuals ranges from asymptomatic to highly lethal, probably reflecting the extent of T cell deficiency. In otherwise healthy individuals, a number of factors are thought to contribute to HRSV (and HMPV) pathogenesis and the observed heterogeneity of disease, including direct viral damage, the host immune response, and other host factors including age, immune status, underlying disease, and genetic polymorphisms affecting host defense.⁹⁶ These are discussed below and in subsequent sections.

Because HRSV can readily infect and cause disease during the first months of life, young age must be considered as a factor in pathogenesis (e-Fig. 38.7). Maternal antibody and immunologic immaturity result in reduced immune responses during infancy (see Immunity section in this chapter), reducing the ability to control the infection. Immune responses in the neonate and young infant can have a reduced Th1 component, which is protective for the fetus prior to birth but can contribute to a Th2 bias in early infancy,^{3,121} and which may contribute to an inflammatory response in the lower airways. The small diameter of bronchioles in infants makes them particularly susceptible to obstruction by edema, secretions, and immune and exfoliated cells.²⁶² Infancy is a time of considerable lung growth and development.¹⁸⁹ Developing lungs may be more susceptible to disease and to long-term effects on lung function. For example, infants with severe HRSV infection express increased levels of neurotrophic factors and receptors.⁵⁵⁸ Studies in a rodent model suggest that this can lead to remodeling of neural networks that innervate the respiratory mucosa, contributing to recurrent airway inflammation and hyperreactivity.⁴⁴⁹ Children with a history of HRSV bronchiolitis early in life were found to have higher obstructive sleep

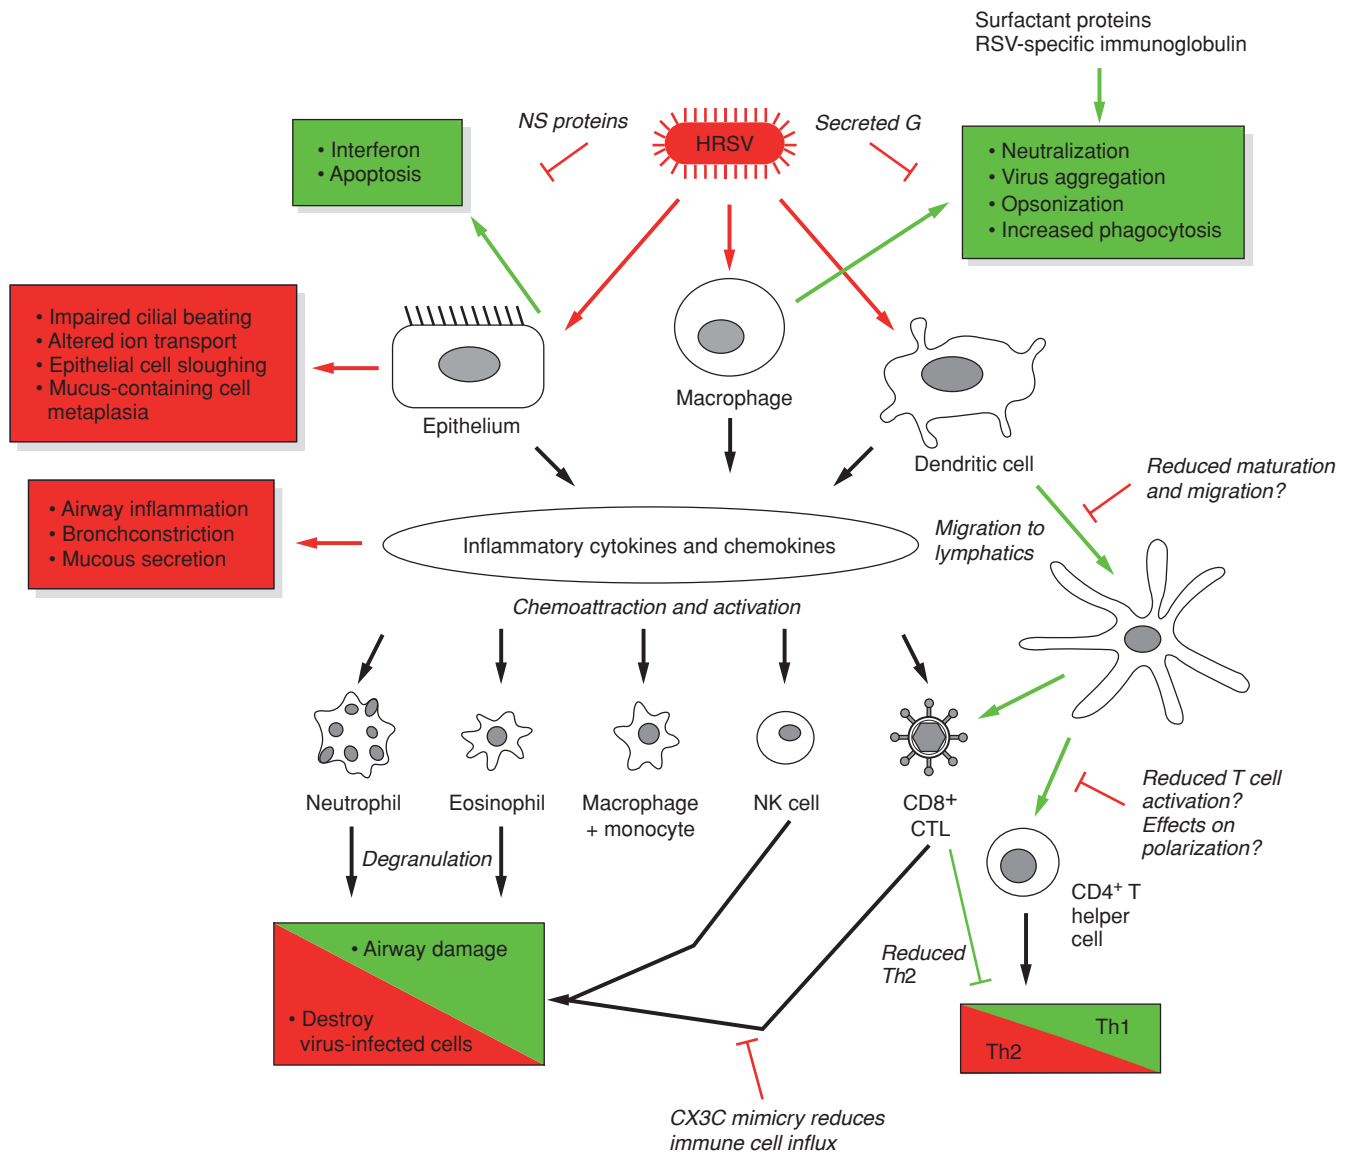

FIGURE 38.8. Factors in human respiratory syncytial virus (HRSV) infection, disease, and immune evasion. In the respiratory tract, the virus (**top**) infects epithelial cells (the major site of virus replication), macrophages, and dendritic cells. Effects that increase virus replication and pathogenesis and/or decrease immune protection are in red; factors favoring protection are in green. **Top right:** surfactant proteins, virus-specific antibodies, and macrophages help restrict infection and spread; antibody-mediated clearance is inhibited by secreted G protein. **Top left:** in infected cells, the viral NS proteins inhibit IFN production and signaling and delay apoptosis. **Center left:** virus infection in epithelial cells impairs their function in maintaining airway fluid level and mucous flow and eventually leads to cell sloughing. **Center:** infected epithelial cells, macrophages, and dendritic cells produce inflammatory cytokines and chemokines that promote airway reactivity and mucous production, attract and activate immune cells, and in some cases may directly induce antiviral effects. **Bottom:** immune cell influx is reduced by viral CX3C fractalkine mimicry. Degranulation by neutrophils (a major inflammatory cell in the airway) and eosinophils, and cell killing by natural killer (NK) cells and CD8⁺ T cells, help restrict infection but also may contribute to disease. **Right:** antigen encounter by dendritic cells leads to their maturation and migration to secondary lymphatic tissue: infection of dendritic cells by HRSV is inefficient and subsequent maturation and migration may be suboptimal. **Bottom right:** dendritic cells induce CD4⁺ and CD8⁺ T-cell activation, polarization, and proliferation: these steps may be reduced due to HRSV exposure. Th2 responses may be suppressed by CD8⁺ T cells and NK cells. (Adapted from Brearey SP, Symth RL. Pathogenesis of RSV in children, In Cane P, ed. *Respiratory Syncytial Virus*. Elsevier: Amsterdam; 2007;141–162.)

apnea and hypopnea indices than control children, which also is associated with increased expression of neurotrophic factors and receptors.⁵¹⁹ There also is evidence from the mouse model that HRSV infection early in life can result in skewed primary and recall immune responses.^{121,541} Other host risk factors are described in the section entitled Epidemiology.

A number of studies, including prospective studies of natural infection, experimental infection of adults with wild-type HRSV, and clinical studies with live HRSV vaccine candidates, have indicated a positive correlation between virus load and disease severity.^{137,138,291,362} although there also are contradictory data.^{37,225,226,615} High nasopharyngeal viral load also was associated with disease severity for HMPV.^{60,362} However, it is not clear whether this correlation reflects pathogenesis due to direct viral damage or a heightened immune response. As noted, studies with *in vitro* human epithelium models indicate that HRSV is not very cytopathic or invasive, compared to influenza virus for example (Fig. 38.6). However, impaired ciliary function and increased cell shedding resulting from HRSV infection would facilitate clogging of bronchioles and alveoli. In experimental infection in adults, the timing of HRSV disease coincided with the timing of viral shedding, suggesting that direct viral damage contributes to disease.¹³⁷ The observation that HRSV (and HMPV) can cause severe disease in immunocompromised cotton rats⁶¹³ and humans^{146,163,233} indicates that severe disease does not depend on an intact adaptive immune system. However, in humans with HRSV LRI, treatment with virus-neutralizing antibodies or the antiviral drug ribavirin that reduced virus replication resulted in limited improvement (see Treatment section), suggesting that factors in addition to direct viral damage are important in pathogenesis, especially by the time that LRI occurs.

It is widely thought that host immunity plays a major role in HRSV (and presumably HMPV) disease. In HRSV-infected cotton rats, treatment with HRSV-neutralizing antibodies rapidly reduced pulmonary titers but had little effect on lung histopathology.⁴⁶³ In contrast, treatment with antiinflammatory glucocorticoids reduced lung histopathology, even though clearance of the virus was slowed, suggesting that the host immune response played the major role in pathogenesis in this model.⁴⁶³ However, the situation is less clear in humans, where treatment with corticosteroids does not significantly reduce disease^{309,439} (see Treatment section). Immune factors that have been suggested to contribute to HRSV disease include (a) an excessive inflammatory response, (b) an overly robust CD8⁺ T-cell response, resulting in excessive tissue damage, and (c) a Th2-biased CD4⁺ T-cell response that is not optimally effective against intracellular pathogens and results in excessive mucous production, airway reactivity, and other effects (see Immune Response). There are supporting and contrary data in each case, as will be shown, and it may be that the contributions of various factors vary in different individuals. Host and viral factors that are suspected to contribute to restriction of HRSV replication and/or to disease pathogenesis, as well as some of the viral mechanisms that subvert or inhibit host immunity, are depicted in Figure 38.8 and discussed throughout this chapter. These general themes likely also apply to HMPV.

IMMUNE RESPONSE

HRSV and HMPV cause acute infections that are restricted and resolved by innate and adaptive immunity. Immune responses

to HRSV and HMPV are broadly similar to those against other respiratory viruses such as influenza and the HPIVs. Infection induces mucosal and systemic virus-neutralizing antibody responses as well as cell-mediated responses. Cellular immunity is particularly important in resolving infection. Secretory and serum antibodies play the primary role in protection against reinfection. With the exception of passively acquired HRSV-neutralizing antibodies, correlates of protection in young infants are difficult to measure and are poorly understood.

Antigens

Postinfection sera from experimental animals or humans contain antibodies that recognize a number of HRSV proteins. However, the F and G proteins are the only virus neutralization antigens and are major, independent protective antigens.¹⁰⁸ This was demonstrated in experiments in which cotton rats or mice were immunized with vaccinia virus recombinants expressing individual HRSV proteins and subsequently challenged with HRSV.^{108,428} F and G were the only proteins that induced neutralizing antibody responses and conferred long-lasting protection. F was more immunogenic and protective than G^{108,428}; the apparent poorer immunogenicity of G may be a consequence of its unusual structure and heavy glycosylation.

A large fraction of MABs raised against the HRSV F protein neutralize infectivity efficiently, and many inhibit fusion.^{32,349} Analysis of viral mutants selected to be resistant to individual MABs mapped five major antigenic sites that mainly involve the F1 subunit.^{113,349} In some cases, mapping has been extended by visualization of antigen-antibody complexes by electron microscopy⁷⁴ or by crystallographic analysis,³⁷⁷ and sites have been mapped on a predicted three-dimensional model of the F protein.⁵¹⁷ Operationally, most of the epitopes of F appear to be conformation dependent, since most monoclonal and polyclonal antibodies raised against native F react poorly with denatured protein, such as in Western blots, and synthetic peptides designed from F are inefficient in inducing neutralizing antibodies or protective immunity.

In contrast, HRSV G has a very different antigenic nature. Most G-specific MABs bind efficiently to denatured G, such as in Western blots, and many bind efficiently to synthetic peptides, suggesting that reactivity does not depend on a complex folded structure.¹⁸⁶ Most MABs against the G protein are inefficient in neutralizing RSV infectivity *in vitro* when tested individually, although neutralization can be achieved with mixtures of MABs.^{365,367} Most G-specific MABs react with some HRSV strains but not others within an antigenic subgroup and thus are “strain-specific”: these MABs often react only with glycosylated G, and their epitopes mostly are in the mucin-like domain in the C-terminal third of the molecule. Other MABs react broadly within a subgroup, and a small number react with viruses from both subgroups: these MABs typically do not depend on glycosylation of G for binding, and their epitopes usually are located in the central conserved region of G.^{365,384} A synthetic peptide representing this central region was protective in mice and calves,²⁹ confirming its importance in immunogenicity and antigenicity. Postinfection human serum antibodies to the G protein were found to be enriched for the immunoglobulin G2 (IgG2) subclass, consistent with G being recognized in part as a polysaccharide antigen.⁵⁸³

Most of the HRSV proteins stimulated memory CD8⁺ CTL from seropositive humans.⁹⁰ However, in both mice and

humans, the G protein is a poor CTL antigen, possibly due to its skewed amino acid content and extensive glycosylation. In the commonly used BALB/c mouse model, the F, N, and M2-1 proteins (of HRSV strain A2) have been shown to induce CD8⁺ CTL responses: the dominant CTL epitope is contained in amino acids 82 to 90 of the M2-1 protein, accounting for approximately 40% of the primary CTL response.³¹² Immunization of mice with vaccinia virus recombinants expressing the N or M2-1 proteins provided protective immunity that was not mediated by neutralizing antibodies and, in the case of M2-1, was confirmed to be mediated by CD8⁺ CTLs.^{108,312} However, protection waned within weeks, suggesting that pulmonary protection by CTLs is short-lived.

For HMPV, the F protein also is a major neutralization and protective antigen, which was shown in studies in which F was expressed by a HPIV1 vector in rodents and nonhuman primates,^{515,539} or by an alphavirus replicon evaluated in mice and cotton rats.³⁹² Surprisingly, vectors that individually expressed the G and SH proteins did not induce detectable neutralizing antibodies or protection in rodents.^{392,514} Similarly, purified HMPV G protein administered to cotton rats did not induce neutralizing antibodies or protection.⁴⁸⁵ Therefore, HMPV may differ from other members of *Paramyxoviridae* in having only a single surface glycoprotein as a major neutralization and protective antigen.

Innate Immunity and Inflammation

The first line of host defense includes the physical barriers of the glycocalyx of the superficial epithelial cells, the secreted mucous layer, and ciliary sweeping. A number of studies have highlighted the role of pulmonary surfactant proteins (SPs), specifically SP-A, SP-C, and SP-D, in restricting HRSV. SPs are lipoprotein complexes produced by type II alveolar cells. SP-A and SP-D have been shown to bind to HRSV, neutralize infectivity (in the case of SP-A), and promote phagocytosis.^{25,192,332} Mice with targeted disruption of SP-A, SP-C, or SP-D exhibited increased pulmonary HRSV titers and disease, which was ameliorated by topical administration of the missing surfactant.^{195,332,333} Genetic polymorphisms in SP-A, SP-B, and SP-D have been associated with severe pediatric HRSV disease.^{150,389,466} Infants with severe HRSV disease were found to have reduced surfactant concentration and function, although it is not known whether this was a cause or a result of severe disease.²⁹³

Toll-like receptors (TLRs) present on the plasma membrane and endosomes³⁰² play a significant role in the host response to HRSV. The HRSV F protein stimulates TLR4 on leukocytes independent of viral replication, leading to activation of the NF- κ B pathway to produce cytokines such as IL-6 and IL-8 and activation of IRF3 to induce type I IFN.³¹⁷ TLR4-deficient mice are less efficient than normal mice in resolving HRSV infection.^{302,317} A number of studies have linked severe pediatric HRSV disease with genetic polymorphisms in TLR4 that reduce its signaling capacity, although other studies did not detect this association.³⁰² HRSV has also been shown to activate signaling from the TLR2/TLR6 heterodimer complex on the surface of leukocytes, resulting in the expression of proinflammatory cytokines, neutrophil influx, and dendritic cell activation in mice.⁴⁰⁷ Mice lacking TLR2 or TLR6 were less able to restrict HRSV challenge compared to normal mice. HRSV also activates TLR3 in epithelial cells, resulting in the production of inflammatory cytokine and chemokines.⁴⁸³ Stud-

ies in TLR3 knockout mice indicated that TLR3 did not make a significant contribution to restricting HRSV replication, but helped prevent IL-13 upregulation and increased mucous production.⁴⁸⁴ Excessive stimulation of TLRs can potentially contribute to pathogenesis: viral infection increases the expression of TLR3 and TLR4, promoting sensitivity both to HRSV and to possible co-infecting viruses or bacteria. In addition to TLRs, the cytoplasmic receptor RIG-I plays a major role in innate responses.^{348,625} Of course, as noted, HRSV and HMPV have mechanisms that suppress activation of these signaling pathways (e-Fig. 38.6).

Infection of epithelial cells by HRSV (or HMPV) alters the cell transcriptional profile markedly, resulting in changes in expression (mostly upregulation) of 900 genes or more.^{22,266,366,632} This was mostly dependent on viral replication. These genes represented multiple biological pathways, showing a broad effect of viral infection. Proteomic profiling of the proteins expressed in A549 epithelial cell cultures following infection with HRSV identified changes in expression for more than 100 cellular proteins, similarly indicating a complex cellular response to infection (the greater number of responding species detected by transcriptional versus proteomic profiling reflects the greater sensitivity of the former method).^{81,402} Comparison of the responses in A549 epithelial cells infected with HRSV, HMPV, HPIV3, and measles virus identified a common core response that mainly involved defense against endoplasmic reticulum stress and induction of apoptosis.⁵⁷⁶

Airway epithelial cells and macrophages exposed to HRSV *in vitro* produce a broad array of proinflammatory cytokines, including IL-1, IL-8/CXCL8, RANTES/CCL5, IL-10, MIP-1 α /CCL3, MCP-1/CCL2, IP-10/CXCL10, IL-6, TNF α , and type I and type III IFNs.^{30,385,386,523} Many of these cytokines have been found in secretions from the upper and lower respiratory tracts of infants with HRSV bronchiolitis.^{56,248} One consequence is the recruitment of immune cells to the infected lung (Fig. 38.8). The total number of immune cells recovered in washes from the upper and lower respiratory tracts of infants was several fold higher in cases of severe HRSV disease compared with uninfected controls.^{157,249,380} Neutrophils were by far the most abundant immune cells present in the airway, comprising 76% to 93% of recovered cells from the upper and lower respiratory tracts, with lymphocytes and mononuclear cells being present at $\leq 10\%$ each and eosinophils at $< 1\%$.^{157,380} Incoming immune cells become activated to express cytokines and other proinflammatory molecules such as cysteinyl leukotrienes that can heighten the inflammatory response.

Inflammation helps control infection but may also contribute to disease (Fig. 38.8), although the picture remains unclear. Studies in mice showed that natural killer (NK) cells are prominent in the early response to infection, are an important source of IFN γ , and have cytotoxic activity against infected cells.²⁶⁷ Granulocytes release factors, such as neutrophil elastase and eosinophil-associated ribonucleases, which can be antimicrobial but also may damage tissue.^{57,480} Increased levels of eosinophil cationic protein and neutrophil elastase have been observed in respiratory washes from infants with severe HRSV disease, indicating the presence and activation of these granulocytes.^{2,188} Mice with eosinophilia due to increased IL-5 expression had increased viral clearance, indicating that eosinophils can be protective.⁴⁴⁸ The amount of mRNA for IL-8—a cytokine that promotes neutrophil chemotaxis and survival—measured in

nasal aspirates of children with bronchiolitis correlated with the severity of disease,⁵¹⁸ and an IL-8 haplotype characterized by increased IL-8 gene transcription was associated with increased susceptibility to HRSV disease.²¹⁹ Bronchoalveolar washes from infants with severe HRSV disease had increased levels of mRNA for IL-9, which is secreted by neutrophils and other cells and promotes inflammation and increased mucous production.³⁷⁹ In infants with severe HRSV disease, the appearance of neutrophil precursors in peripheral blood, preceding their influx into the airways, closely followed the peak of viral load and was coincident with clinical symptoms³⁵¹ (e-Fig. 38.8). These findings suggest that neutrophils in particular have the potential to contribute to both viral clearance and disease. Conversely, however, there also is evidence that, although HRSV may indeed induce high levels of inflammatory cytokines in children hospitalized with HRSV disease, this may not be the dominant factor in severe disease and indeed may be protective.^{37,503} Furthermore, a prospective study of primary HRSV and HMPV infections in infants showed that, although infants infected with either virus had similar disease signs, the levels of inflammatory cytokines induced by HMPV were significantly lower than with HRSV.³²¹ Therefore, although these viruses exhibited similar patterns of disease, they do not share a common pattern of overly robust innate immune responses that might be expected if that is the major determinant of disease.

Macrophages are abundant in the respiratory tract and play important roles in restricting virus replication and modulating the host response. Mice that are genetically deficient in macrophage function, or in which macrophages have been depleted, are less able to restrict HRSV infection and exhibit increased lung inflammation.⁴⁷² This illustrates a key role for these phagocytic cells in restricting the virus as well as in clearing the lung of debris that can cause further damage and inflammation. Macrophages also play an important role in the early response to HRSV infection by producing an immediate release of proinflammatory cytokines.⁴⁵⁷ Studies in mice suggest that macrophages are the primary producers of type I IFN in response to viral respiratory infection in general, with myeloid dendritic cells (DCs) also contributing, whereas pDCs can play a role later in infection if virus replication is not controlled.³¹³

Type I IFN has well-known antiviral effects mediated by signaling through its ubiquitous receptor IFNAR. Type I IFN also is considered to stimulate both innate and adaptive immunity, although these effects can be complex.⁴⁰³ Studies in which bovines were immunized with mutants of BRSV provided evidence of increased humoral and cellular immune responses associated with deletion of NS2, which is the major IFN antagonist of BRSV.⁵⁶⁶ Type III IFN is less well characterized but also has antiviral effects. It generally is produced from the same cell types that produce type I IFN. However, its receptor is expressed mainly on the epithelial cells of the respiratory and gastrointestinal tracts, and thus its effects may be largely limited to those sites.^{144,396} Studies in mice lacking the receptor for either or both type I and III IFN showed that each is involved in restricting replication of respiratory viruses including HRSV,³⁹⁶ although a study with PVM suggested that type I IFN has a greater antiviral role.²⁵²

IFN α/β were detected less frequently and at lower levels in nasal secretions from infants, young children, and adults infected with HRSV, compared to influenza and parainfluenza viruses.^{228,229,374} HRSV infection and replication are

more resistant to prophylaxis or treatment with IFN- α compared to influenza and parainfluenza viruses.^{184,534} Therefore, HRSV may be particularly effective at inhibiting the host IFN response. HMPV induces higher levels of IFN- α/β in mice and is more sensitive to IFN- α than HRSV.²¹⁷

Antibodies

Both serum and secretory antibodies are made in response to HRSV infection. In young infants, the appearance of secretory IgA antibodies usually corresponds with a decrease in HRSV shedding during infection, suggesting a contribution to resolving infection.³⁷⁶ Secretory IgA antibodies are thought to be particularly efficient in restricting HRSV replication. The secretory antibody response is not long-lasting following primary infection, but as individuals grow older and are reinfected, the response is more sustained.²⁹² Experimental infections in adults showed that resistance to reinfection correlated with the titer of HRSV-specific secretory or serum antibodies,^{235,387} and there are similar findings for natural infection.⁵⁸⁵

Studies of prophylaxis in high-risk infants with either intravenous immunoglobulin containing high titers of HRSV-neutralizing antibodies (RSV-IGIV) or HRSV-neutralizing F MAb (palivizumab, motavizumab) have demonstrated the protective effect of serum HRSV-neutralizing antibodies against severe HRSV disease.^{77,214,434} (see Prevention, below). Studies in experimental animals and observations with maternal serum antibodies also illustrate the protective effect of HRSV-neutralizing antibodies (below). The serum antibody response is long-lived (except early in life, as noted below), and peak titers of antibodies detected by ELISA were reached following the second infection in life.⁵⁸² However, serum IgG antibodies gain access to the respiratory tract primarily by the relatively inefficient process of passive transudation. As a consequence, high serum antibody titers are necessary to achieve protection in the respiratory tract. For example, in studies of passively transferred antibodies in the cotton rat model, neutralizing serum titers of 1:390 and 1:3,500 were required to achieve a 99% reduction in HRSV replication in the lower and upper respiratory tracts, respectively.⁴⁶² As another indication of the concentration gradient between the circulation and the lumen of the respiratory tract, the therapeutic effect of passive antibodies in reducing HRSV replication in cotton rats was 160-fold greater when administered directly to the respiratory tract versus systemically.⁴⁵⁹ Studies in humans suggested an antibody concentration gradient of approximately 350:1 between sera and nasal washes.⁵⁸¹ Therefore, protection conferred by serum antibodies obtained by maternal transfer, or prior infection, or passive antibody prophylaxis, depends on a high titer of HRSV-neutralizing antibodies and is less efficient in the upper versus the lower respiratory tract.

Young infants possess maternally derived serum IgG antibodies against HRSV, HMPV, and other common pathogens.¹¹⁴ Epidemiologic studies indicate that HRSV disease in infants born with higher levels of maternal HRSV-neutralizing antibodies was milder and occurred at an older age than in infants with lower antibody levels, suggesting a protective effect.¹⁹⁶ Maternal antibodies are obtained from the mother during gestation by active transport across the placenta beginning at ~26 weeks of gestation and continuing until birth (Fig. 38.9). Infants who are born prematurely have lower titers, increasing their susceptibility to infection and disease. The IgG1 subclass is preferentially

FIGURE 38.9. An idealized diagram based on experimental data illustrating the titer of human respiratory syncytial virus (HRSV)–neutralizing maternal serum antibodies in the fetus¹²⁹ and newborn human infant⁴³⁷ as a function of gestational and postnatal age. This illustration depicts the transplacental transfer of serum antibodies and the subsequent decrease in titer following birth; this diagram shows only the HRSV-neutralizing component of the multivalent maternal antibodies. Courtesy of Dr. James E. Crowe, Jr. Note that absolute neutralizing antibody titers achieved at birth can vary substantially between individual infants depending upon maternal titers.

transferred, but otherwise the titer and specificity of maternally derived IgG antibodies in the full-term neonate are similar to or slightly higher than those of the mother. Thereafter, these antibodies decay with a half-life of approximately 21 to 26 days and protection diminishes. Breast milk may also contribute protective antibodies, although this has not been clearly documented and likely is a minor effect.

In hospitalized infants, HRSV-specific serum IgA and IgG responses were detected 10 days following the onset of illness, and peak titers were achieved at 3 to 4 weeks.⁵⁹⁴ The magnitude of serum and secretory antibody responses to HRSV in young infants typically is reduced compared to older individuals. For example, in a study of infants and young children with a primary HRSV infection, the titers of serum antibodies that bound to the F or G glycoprotein or that neutralized HRSV were 8- to 10-fold lower in individuals of 4 to 8 months versus 9 to 21 months of age.⁴⁰⁹ The frequency of a detectable secretory IgA response to HRSV in infected infants was directly related to age, and these antibodies often were nonneutralizing *in vitro*.^{292,376} The effect of age on the response of serum and nasal wash antibodies to a live attenuated HRSV vaccine is illustrated in e-Figure 38.9. In addition, antibody responses in the young infant are short-lived compared to older individuals: the increases in HRSV-specific IgA and IgG antibodies observed shortly after infection in infants were absent or at very low titer 1 year later.⁵⁹⁴ Therefore, secretory and serum antibody responses are reduced in young infants (<~6 months of age) compared to older individuals with respect to magnitude, neutralizing activity, and longevity. This is particularly relevant to HRSV, since HRSV infection is very common in infancy (*Epidemiology*). Responses to HMPV are assumed to be similar.

Reduced immune responses to HRSV (and HMPV) early in life are due to immunologic immaturity^{3,336} and the immunosuppressive effects of maternal antibodies.^{114,507} Immunologic immaturity has been characterized for a variety of antigens and has been shown to limit innate, antibody, and cellular responses during the first year of life, although these effects are not absolute and adult-like responses can be elicited under

some circumstances.^{3,336} Examination of the human neonatal B cell response to HRSV revealed a bias in the repertoire of antibody gene expression and a dramatically reduced frequency of somatic mutations compared to individuals older than 3 months, which likely contributes to the poorly neutralizing nature of the response in the young infant.⁶¹¹ Immunosuppression by HRSV-specific maternal or passive serum antibodies has been documented in natural infection,⁴⁰⁸ in experimental animals,^{410,411} and in the setting of clinical evaluation of live HRSV vaccines in infants.⁶¹⁷ For example, in the case of live-attenuated vaccines, the titer of maternal antibody had little effect on virus replication in the upper respiratory tract, but suppressed the serum and secretory antibody responses.⁶¹⁷ In mice, passive HRSV-specific serum antibodies suppressed both serum and secretory antibody responses to infection with wild-type HRSV but did not suppress the cell-mediated response and priming for a secondary antibody response.¹¹⁷ Surprisingly, in a cohort of infants younger than 6 months of age who were identified as having very low titers of HRSV-specific maternal antibodies, natural wild-type HRSV infection induced neutralizing serum antibody titers that were indistinguishable from those of individuals aged 6 to 24 months.⁵⁰⁵ This indicates that young infants are capable of mounting a substantial antibody response when maternal antibodies are not present to exert their suppressive role. Therefore, maternal antibodies are beneficial in providing some disease sparing early in life, but also suppress antibody responses.

In adults, natural HRSV infection induced an approximately eightfold rise in serum HRSV-neutralizing antibodies, which declined fourfold during the subsequent year.¹⁶⁵ Titers in uninfected control subjects did not decline during this period, suggesting that there may be a relatively stable set-point, whereas postinfection rises are more short-lived. Interestingly, elderly individuals exhibited a more robust antibody response to infection with HRSV or HMPV compared to younger adults.^{162,584} This indicates that the increased susceptibility that comes with aging is not due to a defect in the ability to produce virus-neutralizing antibodies.

It has been suggested that, in some individuals, HRSV infection induces IgE that may contribute to HRSV disease. IgE—whose production is promoted by the Th2 cytokines IL-4 and IL-13—is bound by receptors on mast cells, and contact with antigen induces the release of mediators including histamine and leukotrienes that stimulate inflammation, rhinorrhea, cough, and wheezing. Increased HRSV-specific IgE and histamine were detected in respiratory secretions from HRSV-infected infants with wheezing in concentrations that correlated with the degree of hypoxia.⁵⁹⁵ However, other groups have not found convincing evidence of HRSV-specific IgE,¹²⁶ and its significance remains uncertain.

T Lymphocytes

Experience with patients with deficiencies in cell-mediated immunity has demonstrated its importance in restricting HRSV and other enveloped respiratory viruses.^{178,233,299,600} Immuno-deficient children fail to clear HRSV and can shed virus for months rather than the typical interval of 1 to 3 weeks. Severely immunocompromised adults, such as HSCT recipients or individuals with leukemia, are readily infected with HRSV and have a high incidence of serious disease and death. In addition, HMPV can cause severe disease in HSCT recipients,⁷⁵ although there also can be prolonged shedding without disease.¹³³

In the mouse model for HRSV, depletion of the CD4⁺ and CD8⁺ T-lymphocyte subsets individually or together showed that both are important in clearing a primary infection.²⁰⁹ Both subsets also contributed to disease, with CD8⁺ cells having the greater effect.²⁰⁹ In contrast, depletion of B lymphocytes indicated that HRSV-specific antibodies are not required for clearance of a primary infection in mice, although they reduced disease and were important for restricting secondary infection.²⁰⁷ Although treatment with HRSV-neutralizing antibodies can greatly reduce viral replication in HRSV-infected mice, it was inefficient in eliminating the virus, illustrating the importance of cellular immunity for viral clearance.⁴³¹

In humans, robust CD8⁺ T-cell responses have been documented in the peripheral blood of infants and children during primary and secondary HRSV infections (e-Fig. 38.8), which precedes the migration of these cells to the respiratory tract.^{249,250} Infants with severe HRSV disease have increased numbers of T lymphocytes in the airways, with a greater abundance of the CD8⁺ versus CD4⁺ subset, and a greater proportion of airway CD8⁺ T cells compared with rhinovirus-infected children.^{157,250,380} However, although the number of CD8⁺ T cells was increased by infection, they did not constitute a particularly abundant cell population either in fluid recovered from the airways of infants with severe HRSV disease^{157,250,380} or in pulmonary tissue from infants that experienced severe or fatal RSV infection.^{273,596} Increased disease was observed in a severely immunocompromised child with a long-term HRSV infection following transfer of donor lymphocytes.¹⁵¹ However, in infants and children with HRSV LRI, the timing of the CD8⁺ T-cell response did not correlate with disease: specifically, the appearance of virus-specific CD8⁺ T cells in peripheral blood peaked during recovery 9 to 15 days following the onset of symptoms.^{249,351} (e-Fig. 38.8). In addition, the magnitude of the systemic virus-specific CD8⁺ T-cell response did not correlate with disease severity.²⁴⁹ Therefore, although studies in mice suggest that CD8⁺ T cells make an important contribution to HRSV disease, this is less evident from observations in humans.

An increased response of Th2 versus Th1 CD4⁺ lymphocytes (defined by the signature cytokines IL-4 and IFN γ , respectively) may contribute to pathogenic responses to HRSV infection and reinfection. The clinical picture of severe HRSV disease, including airway plugging, wheezing, and long-lasting effects on lung function, has some similarity with asthma, which involves a Th2 bias. As noted, young infants can have a Th2 bias lingering from the prenatal period. In addition, studies in rodents indicate that a Th2-biased response was involved in the enhanced HRSV disease that was associated with a formalin-inactivated HRSV vaccine evaluated in the 1960s (see *Prevention*). However, analogies to asthma and the formalin-inactivated vaccine are inexact because disease in those examples depends on prior sensitization, whereas HRSV disease during natural infection is most severe during the initial exposure and is less severe with repeat exposures.

The evidence for Th2-biased responses in HRSV disease is mixed. In some studies, peripheral blood mononuclear cells from infants hospitalized with HRSV disease exhibited a Th2-biased HRSV-specific recall response when stimulated *in vitro*.^{36,479} However, other studies documented Th1-biased responses⁶² or heterogeneity in responses, with some infants having Th1-biased responses and others Th2.^{328,390} Th2-biased cytokine responses detected in respiratory washes from infants infected with HRSV were significantly higher than from influenza virus-infected infants.⁵³³ A positive association was found between HRSV disease and a genetic polymorphism in the IL-4 gene that increases gene expression.³⁸⁹ Other studies detected Th2-biased responses predominantly in individuals with a history of asthma or allergy, suggesting that Th2 involvement is linked to those with this predisposition.^{296,330} In another study, Th2-biased responses were observed with influenza and parainfluenza virus in addition to HRSV and were greater in individuals ≤ 3 months of age compared to those > 3 months of age, suggesting that this reflects a Th2 bias during the first few months of life but is not specific to HRSV.³¹⁰

Studies in mice suggest that NK cells and HRSV-specific CD8⁺ CTLs play an important role in enhancing Th1 and limiting Th2 responses to HRSV antigens during infection, an effect mediated by secretion of IFN γ and probably other regulatory molecules.^{267,429,525} IFN- α/β also appeared to enhance Th1 and suppress Th2 responses.^{148,403} In addition, HRSV-specific CD8⁺ T cells may reduce virus-induced inflammation through the secretion of IL-10.⁵²⁹

Viral Inhibition and Evasion of Host Immunity

HRSV is able to readily reinfect symptomatically throughout life without need for significant antigenic change, and symptomatic reinfection by HMPV also appears to be common (*Epidemiology*). This is in contrast to influenza A virus, for which symptomatic reinfection usually depends on significant antigenic change. This is widely interpreted as evidence that HRSV (and HMPV) inhibits or skews the development of long-term protective immunity. However, the evidence for this is unclear.

HRSV and HMPV indeed have a number of mechanisms that inhibit host innate and adaptive immunity. Some of these have already been noted for HRSV in particular, including very effective (for HRSV) inhibition of type I and type III IFN production and signaling, inhibition of apoptosis, inhibition of TNF α and NF- κ B signaling, and inhibition of PKR activation

and stress granule formation. HRSV also inhibits signaling from type II IFN (IFN γ) in macrophages.⁵⁰⁰

In addition, studies in the mouse model with HRSV mutants showed that the presence of the fractalkine motif in the G protein has the effect of reducing the pulmonary influx of CX3CR1-bearing leukocytes, including subsets of NK cells and CD4⁺ and CD8⁺ T cells, and thus reduces both innate and adaptive responses to infection.²⁴³ In a separate effect, the central conserved domain of G was shown to reduce activation of TLR2, TLR4, and TLR9 in human monocytes, thus suppressing innate immune responses.⁴⁵³

As another example, presentation of HRSV and HMPV antigens by myeloid dendritic cells (mDCs) may be inefficient. HRSV and HMPV infect human mDCs inefficiently *in vitro* and induce a low-to-moderate level of mDC maturation.^{128,218,325} In the case of HRSV, maturation was partly suppressed by the NS proteins,⁴⁰⁴ but reduced maturation also appeared to be due to insufficient stimulation rather than strong inhibition.³²⁵ In addition, expression of NS1 was associated with a shift toward Th2 polarization, reduced Th17 polarization, and reduced activation of CD8⁺ T cells bearing CD103, a homing integrin that directs CD8⁺ T cells to mucosal epithelial cells.⁴⁰³ In mDCs infected with HRSV or HMPV, upregulation of the CCR7 receptor that is necessary for mDC migration to lymphatic tissue was inefficient.³²⁴ Some studies demonstrated reduced activation and altered polarization of CD4⁺ T lymphocytes *in vitro* in response to HRSV-exposed human mDCs,^{128,218,482} although other results suggest that HRSV does not differ significantly from HMPV, HPIV3, and influenza A virus in this regard.^{323,325} HRSV also can suppress T-cell proliferative responses *in vitro* by direct contact mediated by the F protein.⁴⁹⁴ These observations suggest a variety of mechanisms that might reduce/alter antigen presentation and activation, polarization, and proliferation of CD4⁺ and CD8⁺ T cells, but also suggest that some of these effects may not be unique to HRSV.

However, although HRSV has mechanisms that inhibit host immune responses, this likely is true of most viruses, and it is not clear that this is more pronounced with HRSV. It also is not clear that protective responses to HRSV and HMPV are inherently weak or skewed. As noted, the weak and short-lived immune responses observed in young infants are particular to that population rather than to the virus, and brisk serum antibody responses were observed when the suppressive effect of maternal antibodies was minimized.⁵⁰⁵ Primary infection of seronegative mice and cotton rats with HRSV induces robust antibody and cellular immune responses and long-lived protective immunity.^{208,461} Infection of seronegative chimpanzees with wild-type HRSV or with strongly attenuated live vaccine candidates induced very robust serum antibody titers and protection.^{115,549,603,606} With HMPV, infection of mice or cotton rats results in a brisk neutralizing serum antibody response and clearance of the virus, although there was one report of prolonged virus replication for 60 days.^{6,241} In another report, infection of cynomolgus macaques with HMPV resulted in neutralizing serum antibody responses that waned substantially over the course of several months, and provided poor protection against a homologous challenge 8 months later.⁵⁷³ However, in human adults, titers of neutralizing antibodies to HMPV and HRSV are quite high.^{162,165} Importantly, reinfection with either virus usually is associated with substantially reduced disease (see *Epidemiology* section), indicating that

prior infections induce substantial protection against clinically significant disease. Therefore, the extent to which HRSV and HMPV inhibit or subvert the host protective response remains unclear.

The ability of HRSV and HMPV to reinfect might also reflect evasion of protective immunity. For example, the secreted form of the HRSV G protein was shown to help the virus escape antibody-mediated neutralization, serving as an antigen decoy to spare the virus from neutralizing antibodies, and acting to reduce antibody-mediated clearance by immune cells.⁷⁰ Because other common respiratory viruses do not appear to encode secreted forms of a major protective antigen, this may help explain the relative insensitivity of HRSV to restriction by maternal antibodies in HRSV-naïve young infants, and also would facilitate reinfection later in life.

Features of the major viral protective antigens may help evade immunity. As noted, HRSV G is less efficient than F as a neutralization antigen, and HMPV G does not appear to induce neutralizing antibodies or protection. HRSV G also generally appears to be a poor inducer of CD8⁺ CTLs. Clonal analysis of the human antibody response to HRSV F showed that half of the repertoire was against nonnative protein, suggesting that a substantial proportion of F is produced in an unfolded form that may divert and reduce the immune response to the folded, functional form that is packaged in the virion.⁴⁸⁷ Although antigenic differences in HRSV or HMPV are not necessary for reinfection, they do increase its efficiency.⁵⁸⁹

The tropism of HRSV (and HMPV) also may help evade immunity. Restriction of virus replication to the superficial layer of the epithelium, apical budding, and low invasiveness and low cytopathogenicity likely delay and reduce the exposure of viral antigen to the host immune system⁶³¹ (Fig. 38.6). Dendritic cells can sample antigen in the respiratory lumen, but poor infectivity and poor induction of CCR7, as noted, would reduce antigen presentation. As noted, serum antibodies are not efficiently transported to the lumen, and local secretory antibodies can be short-lived. In addition, a number of reports have indicated that CD8⁺ CTLs are functionally downregulated in the lung. This was originally suggested to reflect immune inhibition by HRSV,⁸⁵ but further studies showed that this effect does not appear to be specific to HRSV but rather is a property of the tissue.^{141,211,570} This probably is a mechanism to reduce lung injury, but would also reduce immune protection. Therefore, evasion of host immune responses likely contributes to infection and reinfection by HRSV and HMPV.

EPIDEMIOLOGY

Infection of Infants and Young Children

HRSV is the most important global cause of severe acute viral LRI in infants and young children. In a benchmark surveillance study from 1957 to 1976 in Washington, DC, HRSV was detected in 23.3% of hospitalizations for respiratory tract disease in infants and young children, compared with 11.5%, 6%, 3.2%, and 5.2% of hospitalizations with HPIV3, HPIV1, HPIV2, and influenza A virus, respectively.^{297,412} Similar values for the proportion of ARI hospitalizations attributable to HRSV in infants and young children were obtained in more recent studies.^{258,263} HRSV infection was detected in 43% of

those hospitalized with a diagnosis of bronchiolitis and in 25% of those with pneumonia, compared to 11% of those hospitalized with bronchitis and 10% of those with croup.^{297,412} HRSV infection is more likely to result in pediatric LRI compared to influenza or HPIV1, HPIV2, or HPIV3.¹⁷⁹ Shay et al.⁵⁰² estimated that there are 73,400 to 126,306 annual hospitalizations for HRSV pneumonia and bronchiolitis in infants younger than 1 year of age in the United States; more recent estimates by Hall et al.²³⁶ and Lee et al.³²⁹ for annual hospitalizations for HRSV disease in children younger than 5 years of age were 57,527 and 113,000, respectively. The burden of HRSV disease is not confined to hospitalization. In the United States, an estimated 2.1 to 4.2 million children younger than the age of 5 years (representing 10% to 20% of that age group) receive medical care each year for HRSV-related illness.^{236,329} Hall et al.²³⁶ estimated that this involves 517,747 (1 of 38) visits to the emergency room and 1,534,064 (1 of 13) primary care office visits, in addition to the hospitalizations already noted.

Although less is known about the burden of HMPV disease, a prospective study of infants hospitalized for ARI or fever without localizing symptoms in Nashville, TN, and Rochester, NY, found that 3.8% of 1,104 such hospitalizations were associated with HMPV.⁶⁰⁷ Other retrospective studies at referral hospitals suggested that approximately 5% to 10% of specimens from children hospitalized with ARI or fever were positive for HMPV RNA by RT-PCR. In a cohort of more than 2,000 subjects aged 0 to 5 years followed during a 25-year period at Vanderbilt University Medical Center, approximately 12% of outpatient LRI was associated with HMPV infection, which was second only to HRSV in this population.⁶⁰⁸

Worldwide, HRSV was estimated to cause 33.8 million new cases of LRI in children younger than 5 years of age in 2005, accounting for 22% of all LRI in that age group.^{221,417} This resulted in an estimated 3.4 million hospitalizations and 66,000 to 199,000 deaths due to HRSV-associated LRI. These are probably underestimates, since HRSV testing was incomplete and community LRI was undercounted. Although the contribution of HRSV to morbidity and mortality in resource-limited settings is less well understood, a recent study in coastal

Kenya showed that HRSV was the predominant virus detected among hospitalized children with severe pneumonia.³⁹

HRSV infection is more common in infancy than is infection with other respiratory viruses. Prospective studies have demonstrated that 50% to 69% of infants are infected during the first year of life,^{197,253,297} and virtually all are infected by age 2.¹⁹⁷ Primary infection is usually symptomatic, and 25% to 40% of primary infections result in LRI.^{197,286} Hospitalization for severe HRSV disease is most frequent between 6 weeks and 6 months of life, with a peak incidence at 1 to 3 months of life (Fig. 38.10). HRSV also causes a substantial disease burden in children beyond the first year of life: of the primary care visits for HRSV disease in infants and children younger than 5 years of age, 61% occurred between the ages of 2 and 5 years.²³⁶ Primary infections with HMPV typically occur slightly later than HRSV, with peak hospitalization occurring at about 6 months of life.^{59,401,575} HMPV seropositivity is almost universal by age 5 years.⁵⁷²

Reinfection with HRSV is frequent during the first few years of life, more so than with other respiratory viruses. For example, in the prospective study noted above,¹⁹⁷ 47% and 45% of the children during the second and third years of life, respectively, were re-infections. In a day care center study in which 98% of HRSV-naïve infants and young children were infected when exposed to HRSV during an outbreak, the frequency of reinfection during the two subsequent yearly epidemics was 74% and 65%, respectively.²⁵³ Therefore, children often are infected two or more times with HRSV during the first few years of life. Reinfection is usually symptomatic. One study found that LRI could occur during either the first or second infection early in life, whereas for subsequent infections there was a considerable reduction in disease severity reflecting increasing protective immunity.²⁵³ Recurrent infection with HMPV also is thought to be common. In infants, the second HMPV infection can present with upper or lower respiratory tract disease.⁶¹⁰

Mortality due to HRSV is uncommon in children in developed countries, although mortality is increased substantially in infants with congenital cardiac or pulmonary disease, or immunodeficiency or immunosuppression. There are no

FIGURE 38.10. Age at time of hospitalization for human respiratory syncytial virus (HRSV) disease at the Johns Hopkins Hospital during 1993–1996. The red bars indicate more severe disease. (Adapted from Karron RA, Singleton RJ, et al. Severe respiratory syncytial virus disease in Alaska native children. RSV Alaska Study Group. *J Infect Dis* 1999;180:41–49.)

exact determinations of the overall death rate, but the estimates appear to have dropped over time. A survey from the mid-1970s estimated the fatality rate at 0.5% to 2.5% of hospitalized children with HRSV infection,⁹¹ and in 1985 HRSV was estimated to be responsible for 4,500 pediatric deaths annually in the United States.³⁸¹ More recent estimates are as low as 0.3% of hospitalized children. In the United States, the pediatric mortality rate was estimated to be 5.3 and 0.9 per 100,000 per year for individuals younger than 1 year of age and 1 to 4 years of age, respectively, totaling approximately 300 deaths per year.⁵⁵³ This likely reflects improvement in supportive care.

Major risk factors for pediatric HRSV infection and disease include increased exposure (day care attendance, siblings younger than 5 years of age, and admission to the hospital during HRSV season), low titers of maternal antibodies, lack of previous HRSV infection, premature birth (<36 months gestation, and especially <28 months),^{40,122} young age, chronic lung disease,²¹² congenital heart disease,³⁵² neuromuscular diseases, and primary immunodeficiency disorders.^{178,375} Other factors include asthma or a family history of asthma, poverty, exposure to tobacco smoke, and male gender. In one study, the estimated number of HRSV hospitalizations per 1,000 during the first year of life was 388 for infants with chronic lung disease, 92 for those with congenital heart disease, 66 for those born at 29 to less than 33 weeks, and 30 for term infants with no underlying disease.⁶¹ Fatality rates for children born prematurely or having underlying pulmonary or cardiac disease were similarly elevated.⁵⁹³ However, it is important to note that 50% to 70% of HRSV hospitalizations occur in previously healthy full-term infants.^{61,455}

Very high rates of hospitalization can occur in certain populations. In American Indian and Alaska Native children, the risk of hospitalization for HRSV is 3 to 5 times greater than that of the general United States pediatric population,^{51,289} and high rates of severe HRSV disease have been observed in other aboriginal populations.

Various host genetic factors have been implicated in susceptibility to pediatric HRSV disease. A recent study found an increased concordance of severe pediatric HRSV infection in identical versus fraternal twins.⁵⁵⁴ A number of studies have described positive or negative associations of severe pediatric HRSV disease with polymorphisms in a variety of host genes, notably ones involved in innate immunity and the Th2 subclass of CD4⁺ T lymphocytes. These include genes for surfactant proteins, TLR4, IL-4, IL-8, IL-9, IL-10, IL-13, IL-18, RANTES (CCL5), CX3CR1, vitamin D receptor, nitric oxide synthetase, transcription factor Jun, IFN α 5, and other innate immunity genes.^{268,346,389,498,508} These gene-association studies remain preliminary and are sometimes contradictory, probably because the study sizes were too small to validate associations, but they suggest that a number of genes contribute to resistance or susceptibility to severe HRSV disease.

Infection of Adults

HRSV reinfects adults at a rate of approximately 5% to 10% per year.^{159,163} Reinfection is more frequent in adults with increased exposure to the virus: during a typical HRSV season, 25% to 50% of health care workers are reinfecting, and family members of sick children are readily reinfecting. It is likely that adults become susceptible to re-infection as titers of secretory and serum HRSV-neutralizing antibodies from previous

exposure decline with time.^{166,235,387} HRSV is considered to be second to influenza as a cause of medically significant respiratory tract disease in adulthood. For example, in a study in the United Kingdom using RT-PCR to identify pathogens in various age groups with medically attended respiratory disease, in individuals 15 years of age or older, HRSV was identified in 11% to 22% (depending on the year) of cases compared to 16% to 43% with influenza virus.⁶²⁹ Hospitalization of healthy, nonelderly adults for HRSV disease is rare. However, severe disease and even death due to HRSV can rarely occur in young, previously healthy adults.⁵⁰¹ HMPV reinfection occurs in 1% to 9% of adults each year, with a wide disease spectrum ranging from asymptomatic to severe respiratory disease.^{158,586}

HRSV is an important cause of morbidity and mortality in the elderly (>65 years of age). In one study, HRSV infection was associated with 10.6% of hospitalizations in the elderly for pneumonia, 11.4% for chronic obstructive pulmonary disease, 5.4% for congestive heart failure, and 7.2% for asthma.¹⁶³ Low serum neutralizing antibody titer was associated with increased risk of hospitalization.⁵⁸⁷ HRSV is estimated to cause on average 17,358 deaths annually in the United States, with 78% of these deaths in adults older than age 65.⁵⁵³ Therefore, in more affluent countries, deaths due to HRSV are much more frequent in the elderly than in the pediatric population, whereas in less affluent countries the pediatric burden is likely to be greater. HMPV also afflicts the elderly. In one study of adult patients hospitalized for cardiopulmonary conditions, 11% had evidence of HMPV infection, and the frail elderly appeared to be at increased risk of severe disease.¹⁶⁰ In another study of elderly adults hospitalized for respiratory tract disease, HMPV was identified in 8% of cases (ranging from 4.4% to 13.2%, depending on the year), compared to 10.5% for influenza A and 9.6% for HRSV.¹⁵⁸ Immune senescence,⁴⁴⁰ resulting in a reduced ability to control infection, presumably is an important factor in the increased severity of HRSV and HMPV disease in the elderly.

Other High-Risk Populations

HRSV is important in adults and older children with underlying pulmonary or cardiac disease or who are severely immunocompromised, especially with T-cell deficiencies.^{406,600} Patients with congenital immunodeficiencies such as severe combined immunodeficiency diseases are at high risk. The mortality rate associated with severe HRSV disease in adults with profound immunosuppression due to leukemia or HSCT can be as high as 80% to 100%.⁶⁰⁰ The severity of disease depends on the type and magnitude of immunosuppression.^{247,599} For HSCT recipients, HRSV infection that occurs preengraftment is associated with the highest risk of pneumonia and death, but mortality also is high in those who develop pneumonia postengraftment.²⁴⁷ HMPV also can cause severe disease in individuals with hematologic malignancies and in HSCT recipients,⁶⁰⁹ although mild or asymptomatic infections also can occur. Both HRSV and HMPV can cause severe LRI in lung transplant recipients, and HRSV has also been associated with chronic rejection and the development of bronchiolitis obliterans in these patients.⁶¹² HRSV is the leading viral cause of hospitalization and reduction in pulmonary function for children with cystic fibrosis.^{11,220,261} The relationship between HIV infection and HRSV disease appears to vary by setting. In the United States, prior infection with HIV does not appear

FIGURE 38.11. Variation in human respiratory syncytial virus (HRSV) epidemics during three successive years at the Johns Hopkins Hospital, based on pediatric hospitalizations for HRSV disease.

to increase the morbidity and mortality associated with HRSV infections in children, although prolonged viral shedding has been reported.²⁹⁹ However, in South Africa, HRSV has been reported to cause greater morbidity and mortality in HIV-infected than HIV-uninfected children, although the contribution of other illnesses cannot be excluded.³⁵⁷

Epidemics

In temperate climates, HRSV occurs primarily in yearly epidemics of 4 to 5 months duration in the winter and early spring (Fig. 38.11), although continuous activity also has been reported.²⁴⁰ Elsewhere in the world, the HRSV season varies from location to location.⁶²⁸ Globally, HRSV activity is greatest during periods of moderate humidity and either cool (2°C to 6°C) or warm (24°C to 30°C) temperature.⁶²⁸ HMPV also occurs primarily in annual epidemics during the late winter and early spring in temperate climates, often overlapping in part or in whole with the annual HRSV epidemic.^{1,426} However, long-term studies have shown that sporadic HMPV infection occurs year round in temperate areas.^{426,608}

HRSV is highly infectious and easily spread by contact, especially in settings of close interaction such as day care facilities, hospitals, and families. HRSV is introduced into families primarily by a young school-aged child, after which infection spreads to siblings and adults with high frequency. In one prospective study, approximately 40% of all family members older than 1 year were infected after the introduction of HRSV.²³⁰ HRSV is a major cause of nosocomial infection. The rate of hospital-acquired infection for infants and children during an HRSV season was reported to range from 26% to 47% in newborn units and from 20% to 40% for older children. Hospital staff members appear to play a major role in nosocomial spread of HRSV infection. The likelihood that an individual infant or child will acquire nosocomial HRSV infection increases with the duration of stay and the number of individuals housed in his or her room.²²⁷ Outbreaks in units caring for immunocom-

promised patients can be devastating.³⁷⁰ Outbreaks producing LRI in facilities housing institutionalized adults also have been reported.¹⁷⁷

An evaluation of the HRSV strains circulating in distinct geographic regions during the same years found that five to seven distinct lineages or genotypes representing both antigenic subgroups circulated during the same season in a given location.^{444,445} In a given year, the pattern of genotypes frequently is different in different locations. The pattern of local strains gradually changes in successive years. There typically are one or two dominant local genotypes that are replaced in dominance in successive years. In addition, there can be shifts in the predominance of subgroup A versus B occurring in 1- or 2-year cycles.⁵⁸⁹ This presumably reflects an advantage of the heterologous strain in evading previously induced immunity,⁶⁰² but reinfection by the same subgroup also frequently occurs. Therefore, HRSV epidemics do not involve spread of a predominant new strain, as is the case with influenza A virus. Rather, epidemics appear to involve local endemic strains as well as new genotypes introduced from other regions. The introduction and spread of new strains were illustrated by the appearance in 1998 of a new subgroup B strain called BA that contains a 60-nucleotide duplication in the G gene, and which subsequently disseminated across five continents and underwent further evolution.⁵⁶⁰ The pattern of circulation of HMPV is similar: strains from the two subgroups can co-circulate, and there are several reports of an alternating pattern of dominance by the different subgroups.^{1,426}

CLINICAL FEATURES

In the previously healthy term infant who encounters HRSV for the first time at age 6 weeks to 9 months, HRSV infection usually causes URI, sometimes accompanied by fever. In 25% to 40% of such infections, however, the respiratory tract below the larynx also becomes involved.¹⁹⁷ Bronchiolitis

and pneumonia are the primary manifestations of HRSV and HMPV LRI, with laryngotracheobronchitis (croup) occurring less frequently. In those infants in whom LRI develops, there is a prodromal phase of rhinorrhea often accompanied by a decrease in appetite. Cough may appear simultaneously, but occurs more often after an interval of 1 to 3 days. At that time, there also may be sneezing and a low-grade fever. Soon after the cough has developed, the child may begin to wheeze; if the disease is mild, the symptoms may not progress beyond this stage. Examination usually shows moderate tachypnea, diffuse inspiratory crackles, and expiratory wheezes. There is profuse rhinorrhea, intermittent fever, and frequently otitis media.²⁵¹ In most instances, uneventful recovery occurs after an illness of 7 to 12 days (Fig. 38.5). Among infants and children who require hospitalization with HRSV or HMPV, clinical manifestations range from bronchiolitis or asthma exacerbation to severe pneumonia.^{54,401,435} Cough is present in most, fever in 52% to 86%, and wheezing in about half of cases.⁶⁰⁸ In more severe cases, the coughing and wheezing progress, and the child becomes dyspneic. Hyperexpansion of the chest is evident, and there may be intercostal and subcostal retractions. Infants often feed poorly, because they are obligate nose breathers and nasal obstruction and tachypnea prevent adequate respiration during feedings. Severe tachypnea is common, even in the absence of visible cyanosis. In advanced disease, the child tires and hypoxia becomes more extreme, and then listlessness and respiratory failure occur.

Bacterial sepsis and lobar pneumonia are unusual complications of HRSV²³⁴ or HMPV infection, although simultaneous bacterial–viral co-infection does occur.⁵⁵⁵ Trials of pneumococcal vaccine in infants significantly reduced the incidence of severe HRSV LRI³⁵⁵ and HMPV LRI,³⁵⁶ suggesting that there are bacterial–viral interactions that may not be appreciated clinically. In contrast, bacterial otitis media is a common complication of HRSV and HMPV upper respiratory tract infection. HRSV and HMPV are two of the most common precipitating factors associated with otitis media. Most of this disease is due to eustachian tube dysfunction, resulting in bacterial stasis in the middle ear and subsequent otitis media. HRSV and HMPV antigens and nucleic acids have been reported in middle ear fluids.^{425,490}

Most infants who require hospitalization for HRSV or HMPV infection are hypoxemic on admission; in fact, a low reading on pulse oximeter is often cited as the criterion for admission. This hypoxemia is probably due to an abnormally low ventilation/perfusion ratio. In those with underlying cardiac or respiratory disease, the progression of symptoms may be rapid, especially in those with cyanotic congenital heart disease or chronic lung disease.²¹² In these instances, respiratory failure requiring intubation and ventilation may develop on the second or third day of illness. In children younger than 2 years with cystic fibrosis, the consequence of HRSV infection may be prolonged respiratory morbidity.²⁶¹

In the newborn infant, most HRSV infections produce only URI,²³² probably reflecting the protective effects of maternal HRSV-specific serum antibodies against LRI. Bronchiolitis is rare, and severe infection is more often characterized by lethargy, irritability, and fever or temperature instability than by specific respiratory signs.²³² Symptomatic HMPV infection is rare in newborns. In infants who were born prematurely, and sometimes in normal infants younger than 6 weeks, frequent apneic spells may occur in response to HRSV infection.⁵⁵⁶

Apnea often is seen even in the presence of minimal respiratory signs and may be the predominant symptom bringing the infant to medical attention. Such apneic spells, although often recurrent during the acute infection, are usually self-limited and rarely cause neurologic or systemic damage. Exceptions to this occur, however, and such episodes should be an indication for hospitalization and careful medical supervision with respiratory monitoring.

HRSV has been detected in the lungs of a percentage of children dying suddenly and unexpectedly (sudden infant death syndrome [SIDS]). However, there is no statistically significant association between HRSV and SIDS, and the detection of HRSV in some SIDS cases likely reflects its prevalence as well as the historic concurrence of the peak incidence of both HRSV infection and SIDS in winter months.¹¹⁹ An association between HMPV and SIDS has not been reported.

Abnormalities in pulmonary function are common after HRSV bronchiolitis or pneumonia and may persist for 7 to 10 years or even into adulthood.^{231,280,347,422,509,528} Recurrent wheezing may be common after HRSV bronchiolitis or pneumonia and has been reported in 10% to 50% of former patients,⁸³ but is rarely of great severity. A large case–control study of 200 children hospitalized for bronchiolitis or pneumonia (half of which was due to HRSV) showed that 7 years later there was a significant tendency toward decreased pulmonary function, recurrent cough, wheezing, school absenteeism, asthma, and bronchitis in both of the previously hospitalized groups.³⁹³ Postexercise or pharmacologically induced bronchial lability also is increased, despite an absence of symptoms.⁵¹³ The pulmonary function deficit is partially responsive to bronchodilators, indicating a bronchospastic component.⁸³ Most of these studies did not observe a link between these lingering respiratory abnormalities and allergic sensitization and the development of persistent asthma, but other studies have suggested such a link,^{509,510} and this remains an area of controversy. To date, no such epidemiologic links have been reported for HMPV.

It remains unclear whether infection with HRSV (and possibly HMPV) causes subsequent abnormal pulmonary function, or whether the abnormalities observed existed before infection and indeed may have contributed to disease. For example, Martinez et al. measured pulmonary function in infants at birth or shortly thereafter and found a strong correlation between prior reduced function and the development of bronchiolitis with wheezing on HRSV infection.³⁶⁴ This correlation persisted in children in whom at least one additional lower respiratory infection developed during the first 3 years of life.³⁶⁴ It is likely that respiratory disease and recurrent abnormalities in children are due to multiple factors. These include prior underlying anatomic or functional abnormality that might predispose to initial and recurrent acute bronchiolitis, a tendency to airway hyperreactivity that might predispose to recurrent wheezing, and infection by HRSV or other airway pathogens. Environmental factors such as family smoking may trigger episodes of lower respiratory dysfunction and aggravate long-term or recurrent airway pathology. There is evidence that preventing severe HRSV infections early in life reduces the incidence of recurrent wheezing, suggesting that HRSV can play a causal role.⁵¹² Most pulmonary abnormalities associated with prior respiratory tract infection resolve by 8 to 12 years of age.

Symptomatic HRSV infections are common in normal adults, particularly in medical personnel or in individuals caring

for small children.^{227,230} Such episodes are usually characterized by rhinorrhea, pharyngitis, cough, bronchitis, constitutional symptoms of headache and fatigue, and fever. Disease usually lasts about 5 days but may be more prolonged. In contrast, HMPV infection in adults is often asymptomatic, although the spectrum of clinical illness in symptomatic individuals is similar to HRSV, with hoarseness being particularly prominent in young adults.⁵⁸⁶ In older persons, particularly those with underlying disease, severe LRI may occur with HRSV or HMPV, requiring hospitalization and intensive care. HRSV infection in severely immunocompromised individuals usually starts with URI for 5 or 6 days, with symptoms similar to those of a normal host, but frequently evolves into LRI.

DIAGNOSIS

Differential Diagnosis

The differential diagnosis of HRSV and HMPV infection in young infants must include all other causes of acute LRI. This includes parainfluenza viruses, particularly HPIV3, adenoviruses, influenza viruses, rhinoviruses, coronaviruses, and enteroviruses. In infants younger than 4 months, *Chlamydia trachomatis* also must be considered, which causes afebrile interstitial pneumonia with cough and, in some cases, wheezing. In HIV-infected children, infection with *Pneumocystis carinii* should be considered. Differentiation from bacterial pneumonia may occasionally be difficult, although wheezing is almost never present during infection with pyogenic bacteria, and infants with bacterial pneumonia typically have lobar pneumonia and may have systemic illness associated with bacteremia. In older infants, infections with HRSV or HMPV must be differentiated from other causes of mild respiratory tract infection as well as causes of acute bronchospastic disease, including environmental allergens and aspiration of a foreign body.

In the elderly, HRSV or HMPV infection should be suspected in any patient (with or without underlying cardiopulmonary disease) who has acute bronchitis, pneumonia, or wheezing accompanied with or without a low-grade fever, particularly when such an event occurs as part of a cluster of cases in the winter season.

Presumptive diagnosis of HRSV infection in infants can often be made on the basis of the clinical syndrome combined with the time of year and other epidemiologic features. It is common to observe that other members of the family have respiratory illness at the time of, or just preceding, an episode of HRSV bronchiolitis or pneumonia in an infant. Usually the infant has far more serious illness than other members of the family.²³⁰

Radiographic findings for HRSV and HMPV are common but relatively nonspecific. The radiologic findings on chest radiographs of HRSV and HMPV pneumonia are similar to those of bronchiolitis and reactive airways disease and include hyperaeration, diffuse prominent lung markings due to bronchial wall thickening, and focal areas of atelectasis.

Laboratory Diagnosis

Definitive diagnosis of HRSV and HMPV depends on laboratory tests. Rapid detection of HRSV or HMPV is desirable to guide the use of appropriate infection-control measures and to potentially limit unnecessary antibiotic use. In practice, however, while diagnostic testing is typically performed in aca-

demic centers, it may be used less frequently in community hospitals even in wealthy countries. Few hospitals in resource-limited settings have the capacity for such testing.

The gold standard is isolation of virus in cell culture from nasal swabs, nasal washes, or nasopharyngeal aspirates; however, the lability of HRSV, the slow growth characteristics of HMPV, the expense of the technique, and the increasing availability of assays that rely on nucleic acid detection have made cell culture an increasingly infrequent choice, even for diagnostic virology laboratories in academic centers.

More rapid diagnosis can be made by the detection of viral antigen in nasal swabs or washes. In the direct immunofluorescence assay (DFA), exfoliated cells and other debris are concentrated from secretions by centrifugation, reacted with virus-specific fluorescence-labeled antibodies, and visualized by microscopy. This has the advantage that a knowledgeable technician can confirm that the signal has the pattern expected for infected cells, but the method is time-consuming and requires expertise and a fluorescence microscope. Alternatively, antigen in secretions can be detected by antigen-capture enzyme-linked immunoassay (EIA), in which the sample is incubated with immobilized virus-specific antibodies to capture viral antigen, which is then detected with a second, enzyme-linked antibody. Both DFA and EIA for HRSV are commercially available (with the former being more sensitive than the latter), and DFA is commercially available for HMPV. Another HRSV rapid antigen test available commercially is based on lateral flow immunochromatography.^{194,337} The test sample of secretions is solubilized, mixed with a colored gold-labeled HRSV MAb, and applied to a test membrane on which antibody-antigen complexes migrate laterally and are captured by a line of immobilized HRSV-specific antibody to produce a visible band. The sensitivity of these rapid commercial tests, which produce results in less than 30 minutes, generally is lower than that of DFA, and negative results should be confirmed by DFA. In addition, antigen-based tests in general often have reduced sensitivity in adults due to low levels of viral shedding.¹⁵⁹

RT-PCR of viral RNA for detection of HRSV or HMPV in nasal swabs, nasopharyngeal aspirates, or nasal washes is a useful method of diagnosis for both pediatric and adult populations, because the sensitivity of these assays allows detection of even small quantities of virus. RT-PCR can be used in multiplex formats capable of detecting multiple pathogens. HRSV and HMPV RT-PCR multiplex assays are commercially available, although the procedure is somewhat time-consuming (3 to 6 hours) and requires technical expertise and specialized equipment.^{337,360} RT-PCR is more sensitive than virus culture or antigen assay.²⁵⁷

Serologic methods are used infrequently and provide only retrospective information, since antibody rises are detected by analysis of sera collected 2 to 4 weeks postinfection. Typically, serum antibodies are detected by ELISA or microneutralization assay, with fourfold or greater increases considered indicative of infection.

TREATMENT AND PREVENTION

Treatment

Most infants and children with mild HRSV LRI can be managed as outpatients. Treatment of more severe LRI can be

guided by measurement of oxygenation, monitoring respiratory rate and the trend in respiratory rate, and evaluation of dehydration. Severe respiratory distress, hypoxia, and dehydration are among the indications for hospitalization.

The American Academy of Pediatrics (AAP) has issued evidence-based recommendations for the diagnosis and management of bronchiolitis,⁷ most cases of which can likely be attributed to HRSV or HMPV. Where appropriate, AAP recommendations are cited below.

Symptomatic Interventions and Supportive Care

Inpatient treatment of HRSV infection requires considerable supportive care: mechanical removal of secretions, proper positioning of the infant, administration of humidified oxygen, intravenous fluids, and, in the most severe cases, respiratory assistance with mechanical ventilation. Antibiotic therapy does not improve the outcome in viral pneumonia, does not alter the risk of bacterial complication of viral pneumonia as a superinfection, and should not be used unless there are indications that a bacterial co-infection is present.⁷ The youngest infants infected with HRSV may require monitoring for apnea. Improvements in supportive care clearly have had a major impact on mortality from severe HRSV disease, resulting in the current overall low mortality rate in high-resource settings. Current AAP guidelines advocate the use of supplemental oxygen if the oxyhemoglobin saturation (SpO₂) falls below 90%.⁷ Of all the potential therapeutic modalities described here for severe HRSV disease, supplemental oxygen may be the most accessible for infants in resource-limited settings.⁵⁵²

Corticosteroids have been used in therapy for HRSV bronchiolitis since the 1960s, based in part on their effectiveness in the treatment of acute asthma and on the premise that much of HRSV disease is immune-mediated. However, a meta-analysis of placebo-controlled studies indicated that systemic glucocorticoids on their own provided no improvement in oxygenation, respiratory rate, or length of hospitalization,⁴³⁹ and a large controlled study indicated that inhaled glucocorticoids provided no improvement in wheezing following HRSV bronchiolitis.¹⁵⁴ Current AAP guidance suggests that corticosteroids should not be routinely used in the management of bronchiolitis.⁷

Other antiinflammatory approaches for the treatment of HRSV have also been considered. Acute HRSV bronchiolitis is associated with elevations of cysteinyl leukotrienes in respiratory secretions¹²³; however, the leukotriene receptor antagonist montelukast was not shown to be effective in ameliorating acute bronchiolitis.⁸ Assessment of the utility of montelukast for prevention of post-HRSV wheezing episodes has yielded conflicting results^{49,295,465} and further studies may be warranted.

Drugs used to treat reversible airway smooth muscle constriction in asthma have also been used to treat HRSV infection. Hospitalized infants in the United States frequently are treated with inhaled bronchodilators, but systematic reviews indicate that they provide only modest short-term improvement.^{182,331} This suggests that, in some infants, increased airway resistance is not predominantly due to reversible smooth muscle constriction, but rather is a consequence of obstruction of small airways with mucus, immune cells, and sloughed epithelial cells. Current AAP recommendations are that trial of a bronchodilator may be considered, but that inhaled bron-

chodilators should be used only if there is a demonstrated objective benefit in an individual child.⁷

Antiviral Interventions

Ribavirin, a nucleoside analog, is a broad spectrum antiviral compound the mode of action of which remains unclear,⁵⁰⁶ but which exhibits potent activity against HRSV and HMPV in cell culture and experimental animals.⁶²¹ Ribavirin was approved in 1986 in the United States for use in the treatment of HRSV infection.⁵⁷⁹ A recent review stated that some improvement in subjectively or objectively measured outcome was observed in 7 of 11 published randomized clinical trials of ribavirin, although the size and quality of the trials were highly variable.³⁰⁰ In addition, the drug is difficult to administer via aerosol, can cause anemia, and concerns have been raised about health risks for caregivers.⁴⁷⁷ Currently, the AAP recommends that ribavirin not be used routinely for the management of bronchiolitis, although it could be considered for use in children at risk with severe disease (e.g., those who are immunocompromised or who have "hemodynamically significant cardiopulmonary disease").⁷ Ribavirin has been used empirically for the management of HRSV LRI in HSCT or lung transplant patients,⁵² and was administered intravenously to a lung transplant patient with HMPV.⁴⁷⁰

HRSV disease in young infants can be reduced by prophylaxis with HRSV-neutralizing antibodies (see *Prevention*). Therefore, these antibodies also have been evaluated for therapy of established infection. The most recent studies have utilized the HRSV F MAb palivizumab and the more potent motavizumab administered intravenously.^{320,359} In these studies, palivizumab and motavizumab reduced viral shedding by 10-fold, but a clear effect on clinical outcome has not been demonstrated.²⁶⁵ It is possible that these small studies were not sufficiently powered to observe differences in clinical outcome; alternatively, it may be that much of the LRI observed by the time infants reach the hospital (usually several days into their illnesses) is immune mediated and will not be ameliorated by antiviral treatment. However, antibodies sometimes are used empirically for treating severely immunocompromised individuals, in whom infection can be prolonged,^{164,322} although definite evidence of efficacy is lacking.

Small molecule antiviral drugs specific for HRSV have been developed that target the F, G, N, or L proteins.^{153,343,430,506,530} Four different small molecule inhibitors are undergoing clinical trials for HRSV (www.clinicaltrials.gov, accessed June, 2011). A drug specific to the N protein (AA-60444, previously RSV604)⁸⁸ was evaluated in 2006 in a phase 2 clinical trial in HRSV-infected adult HSCT recipients (clinicaltrials.gov NCT00232635), although the results have not been published. An siRNA that targets the N gene (ALN-RSV01) was evaluated in a phase 2 challenge study in 85 healthy adults (clinicaltrials.gov NCT00496821).¹³⁷ The drug was administered daily by nasal spray for 2 days before and 3 days after HRSV challenge. This resulted in a 38% decrease in the number of individuals infected, and modest but insignificant decreases in viral load in those who were infected.¹³⁷ It will be important to evaluate efficacy in a situation where the drug is administered after, rather than beginning before, infection. This drug also was evaluated in a phase 2 trial of 24 lung transplant recipients with HRSV infection, in which three daily doses were associated with reduced symptom scores and significantly reduced

incidence of bronchiolitis obliterans syndrome.⁶³⁰ An orally administered inhibitor specific to the F protein (BTA9881) was recently evaluated for safety and tolerability (clinicaltrials.govNCT00504907). Reports in the lay press indicated that its safety was unsatisfactory and that further preclinical development is planned. A phase 1 study is planned for 2011 to assess safety, tolerability, and pharmacokinetics for another F protein-specific inhibitor (MDT-637, previously VP14637)^{145,622} that is delivered by a dry powder inhaler (clinicaltrials.govNCT01355016). Small molecule inhibitors are under preclinical development for HMPV.

Other antisense strategies also have been explored against HRSV. Conventional antisense oligonucleotides probably have little potential when administered on their own, but they also have been chemically linked to the 2-5A molecule of the host IFN system.³²⁶ This serves to recruit the cellular antiviral nuclease RNase L to cleave the hybridized RNA. A 2-5A-antisense molecule that targets the conserved GS signals in the viral genome reduced nasal HRSV replication up to 10,000-fold in AGMs when the drug was administered intranasally shortly after infection and during the following 5 days,³²⁶ but further development has not been reported.

Combination therapies also are being developed, involving either the combination of two different antiviral drugs to achieve a higher level of inhibition of viral replication, or the combination of one or more antiviral drugs with an anti-inflammatory drug to restrict replication and reduce immune-mediated disease. This latter combination strategy effectively resolved viral replication and disease in the cotton rat model.⁴⁶³ Similarly, early and aggressive combined therapy involving ribavirin, corticosteroids, and antibodies is being explored for severely immunocompromised adults.^{342,601} In the more usual setting of acute HRSV infection of otherwise healthy individuals, antiviral therapy of a rapidly progressing infection such as HRSV is challenging because by the time the viral agent is identified, it may be too late to control disease solely by inhibiting virus replication.

Prevention Infection Control

Infection by HRSV (and HMPV) can be reduced by hand washing, limiting exposure to infected individuals, and avoiding self-inoculation of nasal and conjunctival mucosa. Nosocomial spread of HRSV has been shown to be reduced by the use of gloves and gowns by caregivers, strict observance of hand washing, active surveillance for HRSV infection, limiting visitors during the HRSV season, and cohorting of infected patients and caregivers.^{223,327,354,416,520}

Passive Immunoprophylaxis Against HRSV

Based on experimental data in animals^{461,462,588} and epidemiologic data in humans¹⁹⁷ indicating that HRSV-neutralizing serum antibodies protected against HRSV LRI, products containing high titers of HRSV-neutralizing antibodies were developed for clinical administration. These products do not necessarily prevent HRSV infection completely, but can proactively restrict replication sufficient to reduce disease. The first product, RSV Immune Globulin Intravenous (RSV-IGIV; RespiGamTM, MedImmune), consisted of immunoglobulin purified from human donor sera that had been screened for high HRSV-neutralizing activity.

It was licensed in 1996 for use in infants and young children at high risk for severe HRSV disease due to prematurity or underlying disease. Administered in monthly intravenous infusions during the HRSV season, RSV-IGIV reduced the frequency of hospitalization for HRSV disease by 55% or more and reduced days spent in intensive care by 97%.^{214,471} However, it had the disadvantages of involving an intravenous infusion, the theoretical risk of adventitious agents, and potential interference with live pediatric vaccines due to the presence of antibodies against common pathogens. RSV-IGIV (RespiGamTM) has been superseded by the development of the MAb palivizumab (see below) and has not been commercially available since 2004.

Palivizumab (SynagisTM; MedImmune) is an HRSV-neutralizing MAb directed against the F glycoprotein that was licensed in 1998. Palivizumab is based on a murine MAb³² that was “humanized” by recombinantly transferring its complementarity-determining regions (~5% of the molecule) onto a human IgG1 backbone (95% of the molecule). Palivizumab is 50- to 100-fold more effective on a weight basis than RSV-IGIV, and accordingly is administered in a much smaller volume by monthly intramuscular injection. Its clinical efficacy is similar to that of RSV-IGIV.⁴³⁴ In infants with cyanotic heart disease, RSV-IGIV was associated with an increased incidence of adverse events²¹⁴—likely due to its large volume and high protein content—but a phase III study demonstrated that palivizumab was safe and effective in preventing hospitalizations for HRSV in children with congenital heart disease.¹⁷⁶ Currently the AAP recommends that high-risk infants receive prophylaxis with palivizumab during the HRSV season. Phase 1 trials also showed that palivizumab was well tolerated based on evaluation in a small number of HSCT recipients.⁵³ There is continued discussion of the cost-effectiveness of palivizumab due to its expense,⁴⁵⁶ but antibodies remain the only effective prophylaxis available for HRSV disease other than infection control. The emergence of antibody-resistant mutants in association with the use of palivizumab has not been a significant problem: they are detected in ~5% of treated individuals from whom HRSV was recovered and appear to have a modest reduction in growth fitness *in vitro*.⁶³⁵

More recently, palivizumab was modified by *in vitro* affinity maturation to create a more potent derivative called motavizumab (MEDI-524 or Numax, MedImmune). Compared to palivizumab, motavizumab differs at 13 amino acid positions. It exhibits a 70-fold increase in antigen binding and a 20-fold increase in neutralization activity *in vitro*, and is substantially more protective in cotton rats and also protects the upper respiratory tract.^{382,620} In a clinical study comparing palivizumab and motavizumab in a group of 6635 preterm infants, infants who received motavizumab had 26% and 55% reductions in HRSV hospitalization and medically attended HRSV LRI (MALRI), respectively, relative to palivizumab.^{77,193} Motavizumab also was evaluated in a placebo-controlled trial in healthy Native American populations (clinicaltrials.govNCT00121108). In this study of more than 2,000 infants, motavizumab was found to reduce HRSV hospitalizations by 83% and outpatient MALRIs by 71%. However, this product was associated with a slight increase in the incidence of hypersensitivity reactions and antidrug antibodies in clinical trials, and its further development for HRSV prophylaxis has been suspended as of this writing. Motavizumab also was evaluated

for the treatment of infants hospitalized for HRSV disease (clinicaltrials.gov/NCT00421304). Prior to the problematic clinical data, motavizumab had been engineered to increase its serum half-life by increasing its affinity for a receptor involved in recycling and sparing antibodies that have been taken up intracellularly for degradation.¹²⁵ This increased the antibody's serum half-life in cynomolgus monkeys fourfold, but it seems unlikely that this derivative will be developed further. Other approaches have sought to develop fully human HRSV-neutralizing MABs using recombinatorial phage display libraries,^{23,397} or from libraries of transformed B cells.⁹³ This latter study is noteworthy because it was able to produce G-specific MABs with high neutralizing activities.

Vaccines

The need for an HRSV vaccine is greatest for infants and the elderly, although a vaccine for toddlers and preschool children might have a substantial impact on emergency room and primary care visits for respiratory illness.^{236,329} Immunization with a pediatric HRSV vaccine ideally should be initiated during the first weeks of life. Because the reduced immune responses characteristic of infancy likely will reduce vaccine immunogenicity and efficacy, multiple vaccine doses will likely be required.

Development of a pediatric HRSV vaccine has been complicated by the phenomenon of enhanced disease that occurred in association with a formalin-inactivated HRSV (FI-RSV) vaccine evaluated in infants and children in the 1960s.^{287,458} This vaccine consisted of concentrated, formalin-inactivated virus that was mixed with alum adjuvant and administered intramuscularly. Immunization with FI-RSV was well-tolerated but proved to be poorly protective. Unexpectedly, upon subsequent natural infection, vaccinees experienced much greater frequency and severity of HRSV disease: 80% of FI-RSV vaccinees required hospitalization compared to 5% in the control group, and two toddlers (ages 14 and 16 months) died of enhanced RSV disease. Autopsies of the two fatalities provided evidence of HRSV replication and pulmonary inflammation.⁴⁵⁸

Subsequent studies, which had the advantage of improved methods and the development of experimental animals models, showed that the immune response to FI-RSV differed markedly from that to HRSV infection. The serum antibodies induced by FI-RSV in the original vaccinees or in experimental animals bound efficiently to HRSV antigen in ELISA but were inefficient in neutralizing infectivity.⁴¹⁵ Studies in experimental animals showed that FI-RSV did not induce a significant CTL response, reflecting its noninfectious nature. Peripheral blood lymphocytes from the original vaccinees exhibited an exaggerated proliferative response to HRSV antigen *in vitro*, suggestive of a heightened CD4⁺ T-cell response to FI-RSV compared to natural infection.²⁹⁸ Consistent with this, subsequent studies in experimental animals showed that FI-RSV induces a disproportionately increased stimulation of the Th2 subset of CD4⁺ T cells compared with HRSV infection.^{109,130,591} These findings indicated that FI-RSV primed for an aberrant, pathologic secondary immune response that occurred upon subsequent infection and viral antigen expression.

The poor neutralizing activity of the serum antibodies induced by FI-RSV likely was a major factor in the lack of protective efficacy, and probably reflects denaturation of neutralization epitopes in the vaccine. It also may reflect deficient antibody affinity maturation due to poor TLR stimulation

by the nonreplicating vaccine.¹³⁵ The formation of antibody-antigen complexes and complement fixation also appears to have contributed to disease, a consequence of the induction of antibodies that did not restrict infection but bound efficiently to antigen.³⁸³ The Th2-biased response also played a key role, demonstrated by the finding that disease enhancement was not observed when FI-RSV-immunized rodents were treated with antibodies to deplete either CD4⁺ T cells or selected Th2 cytokines prior to HRSV challenge.¹¹⁰ The bias toward Th2 appeared to be favored by the lack of stimulation of NK cells and CD8⁺ CTLs, which otherwise downregulate Th2 responses to HRSV antigens, at least in the mouse model.^{267,429} and may also have other immunomodulatory effects.^{429,529} The Th2-bias may also have been enhanced by the presence in FI-RSV of carbonyl groups arising from the formalin treatment.³⁹¹ Therefore, the major elements of disease enhancement include an inadequate protective response, an altered antibody response, and a heightened Th2 response. Similar phenomena of vaccine-related disease enhancement have been described in the clinical use of formalin-inactivated measles virus vaccine⁴⁵² and in experimental animals receiving formalin-inactivated HPIV3⁴³² and HMPV^{131,624} vaccines, and thus does not appear to be specific to HRSV or to *Pneumovirinae*.

Disease enhancement has also been observed in experimental animals that have been immunized with purified HRSV F and G glycoproteins as experimental vaccines.⁴¹⁴ This cautionary finding needs to be strongly considered if nonreplicating HRSV vaccines are developed as potential immunogens for HRSV-naïve infants and children. In contrast, disease enhancement is not observed with natural HRSV infection and reinfection, or in most cases with viral or DNA vectors expressing HRSV antigens. This distinction between killed-virus/subunit HRSV vaccines versus live/vectored HRSV vaccines likely reflects the greater efficiency of the latter in broadly stimulating innate and adaptive immunity, including stimulation of TLRs, NK cells, and CD8⁺ CTLs important in regulating HRSV-specific immune responses. It also is noteworthy that priming for enhanced disease appears to be limited to HRSV-naïve infants and children and has not been observed when nonlive vaccines are used in HRSV-experienced individuals. This has been demonstrated in experimental animals⁵⁹⁰ and in clinical studies described below. Therefore, although a subunit vaccine is contraindicated for RSV-naïve recipients, it could be safely used to boost immunity in older children and adults.

Because of disease enhancement, efforts in recent years to develop an HRSV vaccine for HRSV-naïve infants and young children have focused on live attenuated vaccines. The absence of disease enhancement by live HRSV vaccines has been confirmed in clinical trials in HRSV-naïve infants.⁶¹⁸ Studies in experimental animals including chimpanzees showed that the intranasal route of administration is surprisingly immunogenic and highly protective. It also partially avoids the immunosuppressive effects of serum antibodies.¹¹⁶ Beginning in the 1960s, a series of live attenuated HRSV strains was developed by classic biological methods, notably multiple passages at increasingly low, suboptimal temperature¹⁸⁰ followed by chemical mutagenesis and selection for temperature-sensitive mutants.¹¹⁵ None of the viruses produced by these methods had a satisfactory level of attenuation in 1- to 2-month-old HRSV-naïve infants, although one virus (called *cpts248/404*) was well-tolerated and

immunogenic in an older age group, namely seronegative infants and children 6 months of age or older.⁶¹⁷ Further efforts to obtain satisfactory derivatives by biological means were unsuccessful, and all subsequent vaccine candidates have been made by reverse genetics.

Reverse genetics provides a number of advantages for developing live vaccines, including the means of identifying attenuating mutations in existing viruses,^{104,604} developing new mutations or strategies for attenuation,^{28,41,68,420,549,603} producing viruses with short, well-defined passage histories important for safety,⁵³⁵ increasing genetic stability,³⁶⁹ introducing mutations in desired combinations to incrementally increase attenuation,⁶⁰⁵ and other possibilities such as rearranging the gene order to increase the expression of protective antigens.³⁰⁷

Several attenuated HRSV strains produced by reverse genetics have been evaluated in clinical trials.^{290,619} The lead candidate, a virus called rA2cp248/404/1030ΔSH (e-Fig. 38.10), was well-tolerated in 1- to 2-month-old infants and was moderately immunogenic and highly protective against a second vaccine dose.²⁹⁰ This virus contains a series of point mutations and deletion of the SH gene, is strongly temperature sensitive, and does not form plaques at temperatures higher than 35°C. This degree of temperature sensitivity would preferentially restrict replication in the warmer lower respiratory tract. This virus presently is in phase 1/2 clinical trials. Other attenuated HRSV strains also are in development. One example is the ΔM2-2 virus, which lacks most of the coding sequence for the M2-2 protein. This virus exhibits reduced RNA replication and increased gene transcription and antigen production, which may provide for increased immunogenicity.⁴¹

Another type of live attenuated HRSV vaccine recently evaluated in clinical trials (clinicaltrials.gov NCT00686075, NCT00686075 NCT00493285) uses an attenuated chimera of bovine PIV3, in which the F and HN genes are derived from HPIV3, as a vector to express the HRSV F and/or G proteins from one or two added genes.^{495,540} (e-Fig. 38.10). This provides a bivalent intranasal vaccine against these two important pediatric pathogens. Importantly, BPIV3 and HPIV3 replicate more efficiently and are more stable physically than HRSV. This might facilitate vaccine manufacture and use. However, recent data indicate that the antibody response to RSV F was inferior to the antibody response to HPIV3,^{41a} perhaps resulting from sequence variation in the RSV F transgene (unpublished observations). An analogous approach is being pursued using Sendai virus as vector.²⁸¹ Sendai virus is a murine relative of HPIV1 that has sufficient antigenic cross-reactivity that intranasal immunization protects AGMs against HPIV1 challenge. Sendai virus was well-tolerated in adults and has been engineered to express HRSV antigens as a potential bivalent vaccine against HPIV1 and HRSV.²⁸¹ Other vectored approaches, such as using replication-defective adenoviruses or alphaviruses, also may have promise for pediatric use.

There also is a need for an HRSV vaccine in older children and the elderly, especially for individuals at increased risk due to underlying disease or old age. Live vaccines appear to be too restricted in replication in HRSV-experienced older individuals due to existing immunity.¹⁹⁹ Vectors might not be suitable for repeated vaccinations due to the development of vector-neutralizing antibodies. However, subunit protein vaccines could be suitable, since they do not prime for enhanced disease in RSV-experienced individuals. In addition, prior immunity

can be partially overcome by increased dose.⁴¹¹ A number of HRSV-subunit vaccines have been evaluated in clinical trials. A series of preparations of purified F protein (PFP) isolated from HRSV-infected cells has been evaluated in healthy adults, in children older than 12 months of age with and without underlying chronic pulmonary disease (chronic lung disease of prematurity or cystic fibrosis), in institutionalized and ambulatory elderly subjects, and in pregnant women (immunization during pregnancy had the goal of increasing the titer of HRSV-neutralizing maternal antibodies in the newborn).^{34,167,168,213,405,436,450,563} The PFP vaccines were well tolerated in these populations: acute reactions were minimal, and enhanced disease was not observed. However, HRSV-neutralizing antibody responses were unsatisfactorily low. More recently, a vaccine based on the HRSV F, G, and M proteins purified from HRSV-infected cells was evaluated in an elderly population in conjunction with the inactivated seasonal influenza virus vaccine.¹⁶⁹ This vaccine was moderately immunogenic with or without an alum adjuvant, but is no longer in clinical development.

Another experimental protein-based vaccine, called BBG2Na, consists of a bacterially expressed fragment containing the central conserved domain of the HRSV G protein fused to the albumin-binding domain of the streptococcal G protein. However, in HRSV-naïve infant macaques it was associated with a low level of pulmonary eosinophilia in some animals upon challenge,¹³² and in clinical trials in adults it induced low levels of HRSV-neutralizing antibodies,⁴⁵⁴ with hypersensitivity observed in some vaccine recipients.

Increasing knowledge of the structure and antigenic properties of the HRSV F protein and improved methods of expression and purification may allow for the production of more stable and more immunogenic HRSV F vaccine preparations. As of this writing, the only HRSV subunit vaccine currently being evaluated in clinical trials is an F protein particle vaccine developed by Novavax (clinicaltrials.gov NCT01290419), which is currently undergoing phase 1 evaluation in healthy adults. In other recent work, the HRSV F protein was engineered to remove the fusion peptide, transmembrane region, and cytoplasmic tail, yielding an expressed protein that formed a postfusion trimeric structure that was homogeneous, stable, and highly immunogenic.^{378,536}

Numerous additional approaches to an HRSV vaccine continue to be evaluated in preclinical studies, including synthetic peptides, engineered multiepitope vaccines, antigen expressed by recombinant baculoviruses or produced in plants, antigen fused to carrier proteins such as cholera toxin B subunit, immune-stimulating complexes containing HRSV antigens, liposome-encapsidated HRSV antigen, the use of adjuvants such as CpG oligonucleotides or biopolymer nanoparticles, and vectors including vesicular stomatitis virus, vaccinia virus (Modified Vaccinia Ankara), rhinovirus, Newcastle disease virus, *Mycobacterium bovis* BCG (Bacillus Calmette-Guerin), and *Salmonella typhimurium*. Whether any of these offer advantages remains to be seen. Realistic evaluation of candidate vaccines for HRSV (and HMPV) is complicated by the semipermissive nature of infection of convenient experimental rodent models, which thus gives overly optimistic appraisals of efficacy.

Recombinant HMPVs that lack the M2-2 ORF or G gene have been developed by reverse genetics. These viruses were highly attenuated in rodents and AGMs while retaining a satisfactory level of immunogenicity.^{44,48,66} The ΔM2-2 and

ΔG viruses have levels of attenuation and immunogenicity suitable to be evaluated clinically as candidate live intranasal vaccines. Another approach has been to replace individual genes of HMPV with their AMPV counterparts to create chimeric viruses that are attenuated in primates due to host incompatibility effects of the AMPV gene. A chimera in which the HMPV P gene was replaced by its AMPV counterpart replicated efficiently *in vitro* and appeared to have a satisfactory level of attenuation in AGMs,⁴⁴⁷ and presently is being evaluated in phase 1 clinical trials for safety and immunogenicity (clinicaltrials.govNCT01255410). An attenuated HPIV3 vaccine virus also has been used as a vector to express the F protein of HMPV as a bivalent HPIV3-HMPV vaccine in preclinical studies.^{515,539}

PERSPECTIVE

HRSV is one of the more complex members of *Mononegavirales*. We have general information on many of the roles of the viral proteins and RNAs in the viral replicative cycle, and have some information on how they affect the host cell and host immune system. Continued research is needed to identify and elucidate these mechanisms and their significance to viral biology and the host response.

HRSV is one of the most common and widespread human viruses. HRSV is notable for a historic and tragic vaccine failure, namely the formalin-inactivated vaccine. It also is notable for the development of the successful strategy of antibody immunoprophylaxis against HRSV, which contributed to widespread interest in the development of products based on MAbs. Although the importance of HRSV has been known for more than 50 years, we lack effective vaccines or antiviral therapeutic drugs. There is a need for both, but developing these products for young infants is challenging. A substantial reduction in serious HRSV disease would be a major advance for human health. Vaccines may be improved by new adjuvants, and antiviral drugs may be improved by combination with antiinflammatory therapy.

HRSV is unusual in its ability to efficiently infect and cause disease in early infancy even in the presence of maternal antibodies. The consequences of severe HRSV infection in the context of the immature lung and immature immune system are poorly understood. Severe HRSV disease early in life frequently is associated with lingering abnormalities in pulmonary function, although the causal relationship is uncertain. It also has been speculated that early infection in life can result in long-term deficiencies in the immune response to this virus in some individuals. Further studies of infants who receive passive or (when available) active immunoprophylaxis against HRSV may help to resolve these issues. The relative contributions of direct viral damage and immune factors to HRSV disease remain unclear and likely will vary among individuals, due in part to genetic differences that are being identified. HRSV can reinfect symptomatically throughout life in the absence of significant antigenic change. The extent to which this reflects virus-mediated inhibition or subversion of protective responses remains controversial.

HMPV is a close relative to HRSV that infects somewhat less early in life and causes severe disease less frequently. Many of

the questions regarding disease mechanisms, immune response, and long-term consequences of HRSV infection early in life also apply to HMPV. Research into these important causes of severe LRI in infants and the elderly should yield new insights into pathogenesis and host responses at both extremes of age.

Perspectives and Public Health Considerations

1894–1896 in the district around the town of Borna in Saxony, Germany.³⁵⁸ The name contains the “classifying” letters “RNA,” a classification that was only justified at the end of the 20th century, when the etiologic agent Borna disease virus (BDV) was identified as an RNA virus. BD predominantly affects horses and sheep but other Equidae, certain farm and zoo animals, or companion animals are occasionally also diagnosed with natural BD (reviewed in^{67,113,253,262,310}).

During the first decades of the 20th century, studies of BD focused primarily on defining the etiology, pathology, and pathophysiology of the disease. Initial evidence for a viral etiology was presented by Zwick³⁵⁸ by reproducing the disease with bacteria-free filtrates of brain homogenates from affected horses. Histopathologic studies demonstrated a nonpurulent encephalomyelitis characterized by massive lymphohistocytic infiltrates affecting the gray, and to a lesser extent, the white matter of the central nervous system (CNS), reactive astrogliosis, and intranuclear eosinophilic, so-called “Joest-Degen,” inclusion bodies (described in detail in^{88,141,142,294}). Pathologic changes were preferentially localized in the limbic system, most likely resulting in the observed behavioral disturbances.^{135,262} Detailed studies have been performed on the spectrum of susceptible host species and on the manifestations of the infection. Transmission experiments between naturally infected horses and sheep as well as other host species—including rabbits, guinea pigs, rats, chickens, and monkeys—established the infectious nature of the BD agent and confirmed that the same agent afflicted horses and sheep.^{113,181,205,223,262,358,359}

Interest in BD and its causative virus lapsed until the late 1970s/early 1980s, when the optimization of tissue and cell-culture techniques for propagating the agent paved the way for work on the identification of the agent and on mechanisms of its pathogenesis in rabbit, rat, and tree shrew models.^{177,191,203,308} Milestones in pathogenesis included the adaptation to Lewis and Wistar rats, the demonstration of an age-dependent outcome in experimentally infected rats,^{128,203,206} and the recognition of T-cell–dependent immunopathology.^{128,203,204,257,258,313,318} Narayan’s observations of a biphasic disease in adult-infected rats characterized by initial hyperactivity and followed by hypoactivity prompted efforts to determine whether humans were infected with a related agent. Serologic findings suggestive of a potential role for BDV in affective disorders²⁶³ intrigued many investigators (including the authors of this chapter), resulting in new efforts to identify the causative agent and explore the pathobiology and epidemiology/epizootiology of BDV infection.

However, the causative agent remained elusive until the late 1990s, when BDV was isolated and classified as a negative, single-stranded, nonsegmented RNA virus, the first

HISTORY

The syndrome we know as Borna disease (BD) was first described in European veterinary textbooks in the 1700s^{331,358} as a disease of farm horses using various names like Hitzige Kopfkrankheit (German; “hot-headed disease”) or Seuchenhafte Gehirn-Rückenmarksentzündung (German; “epidemic encephalomyelitis”). The contemporary name Borna disease was coined after the occurrence of major outbreaks in the years

member of the new family *Bornaviridae* in the order *Mononegavirales*.^{27,44,51,176,258,277,281,326} With the advent of reverse genetics systems to produce infectious cDNA clones, detailed molecular analyses of the BDV genome and its gene products, regulation of their expression, and detailed pathogenicity studies using constructs stably expressing fluorescent proteins became possible.^{1,52,220,282,286,353}

In the first decade of the 21st century, a novel BDV, now designated avian bornavirus (ABV), was identified in parrots with proventricular dilatation disease (PDD).^{131,152} PDD is a progressive, variably contagious and often fatal disease of domesticated and wild psittacine birds worldwide. Typical clinical signs such as gastrointestinal (GI) dysfunction and associated wasting with or without neurologic symptoms are caused by nonpurulent inflammation of the enteric, autonomic, and central nervous system (CNS). A viral etiology for PDD has been assumed for over 40 years; recent work provides evidence for the etiologic role of ABV in the development of clinically manifest PDD. ABV has been detected worldwide in many captive parrots but also in other nonpsittacine species.^{55,112,132,217,343}

Until recently, it has been believed that no endogenous nonretroviral viruses exist in animal genomes. Surprisingly, endogenous elements homologous to BDV genes were detected in the genomes of bats, elephants, fish, lemurs, rodents, squirrels, primates, and humans.^{11,133} Although phylogenetic analyses indicate that bornaviruses infected primates at least 40 million years ago, there is only controversial data to support current infection of humans. Indeed, a recently published multicenter study used a wide range of molecular and serologic methods to analyze well characterized samples from subjects with schizophrenia and affective disorders, finding no evidence for human infection with a virus similar to either of the two currently known bornaviruses, BDV and ABV.¹³⁴

THE VIRUS

Taxonomy

Although the syndrome known as BD has been described since the 1700s, its causative agent, BDV, eluded characterization until the late 1980s, when the application of a novel technique, subtractive cDNA cloning, yielded the first cDNA clones of the agent.^{176,326} Thereafter, analysis of concentrated, partially purified virus preparations^{24,251} led to the identification of BDV as a nonsegmented, negative-strand RNA virus, distantly related to rhabdo-, paramyxo-, and filoviruses.^{27,44} Identification of distinctive features including nuclear replication and transcription,^{24,42,258} differential use of transcription initiation and termination signals,^{27,276} and the use of alternative mRNA splicing^{27,45,281} resulted in the creation of a new family *Bornaviridae* within the order *Mononegavirales* in 1996.²⁴³ BDV is the prototype of the family and was its sole member until a new species, ABV, was discovered in 2008.^{131,152}

Morphology and Physical Characteristics

Spherical, enveloped particles of 80 to 100 nm with an electron dense core have been visualized by electron microscopy (EM) in extracts of BDV-infected cultured cells.^{159,356} ABV viral particles of 83 to 104 nm in diameter have been detected in the brain, eye, or small intestine of ABV-infected birds and detection of

comparable particles 25 years ago led to the conclusion that PDD is due to a virus infection.^{132,185,352} Smaller structures also identified in these extracts presumably represent defective particles. No similar structures have been reported in tissues or fluids from infected mammals.^{3,40,270} The virion M_r and the $S_{20,w}$ are not known; partially purified virus has a buoyant density of 1.15 to 1.22 g/cm³ in CsCl, 1.18 to 1.22 g/cm³ in sucrose, and 1.13 g/cm³ in renografin.^{47,84,216,251,356} Virus infectivity is only marginally affected after 24 hours in serum or by incubation at 37°C. In tissues and cell-free virus preparations the virus can be more stable than in culture extracts, and depending on the mode of desiccation, dried preparations can remain infectious for months (tissue at ambient temperature) to years (brain suspension under vacuum).^{47,177,179,205,358,360} At 4°C BDV infectivity is stable for more than 3 months. BDV can withstand both alkaline and acidic environments, but is most stable at neutral pH.^{47,70,114} Heating to 56°C for more than 3 hours inactivates the virus and common disinfection methods are appropriate as BDV is sensitive to organic solvents, detergents, pH below 4, and to UV light.^{47,63,113,114,203,205,216,358}

Genome

The bornaviral genome is a negative sense, single-stranded, nonsegmented RNA comprising approximately 8,900 nucleotides (nt) that includes six major open reading frames (ORF) with structural proteins in a 3' and the viral polymerase in a 5' position.^{27,131,152,208,230} Short noncoding complementary sequences are found at the termini. Unlike other nonsegmented negative-strand (NNS) RNA viruses, bornaviruses lack specific intergenic regions and instead have mostly overlapping ORFs (Fig. 39.1). The first transcription unit encodes the nucleocapsid protein (N). N exists in two isoforms, p40 (40 kDa) and p38 (38 kDa), that differ in the presence or absence of an amino terminal basic sequence that mediates nuclear localization.^{156,245} Although nucleocytoplasmic shuttling can be deduced from immunohistochemical and *in situ* hybridization results for ABV,^{340,341} there is no proof for the existence of N isoforms in ABV.^{92,327,328} The viral phosphoprotein (P, p23) and the regulatory X protein (X, p10) are encoded by the second transcription unit.³³⁹ The 5' end of the P ORF overlaps with the 3' portion of the X ORF in the +1 reading frame, an organization that resembles the P/C/C' organization of the second gene of vesiculoviruses.^{167,307} However, BDV X is the first ORF in the RNA transcript and there is no evidence of co-transcriptional mRNA editing, a mechanism used by some paramyxoviruses to regulate expression of multiple reading frames from their second transcription unit.^{160,321} The first and second transcription units of bornaviruses overlap, because the transcription start S2 is located upstream of the termination/polyadenylation signal T1 (Fig. 39.1).²⁷⁶ The start S3 of the third transcription unit is located 2 nt downstream of T2 and generates multiple transcripts for the matrix protein (M, p16), the type I surface glycoprotein (G, p57), and the L-polymerase (L, p190). The G ORF overlaps the M ORF in the +1 reading frame. The L gene initiates with a short ORF of 6 amino acids (aa) that is spliced to the large 5' ORF (Fig. 39.1).^{281,334}

Bornaviruses are phylogenetically distinct from other taxa. Sequence divergence between strains of BDV and ABV is less than 20%, while divergence between BDV and ABV is greater than 30%; thus, they are classified as different species.^{131,152} The only region where bornaviruses have significant sequence

FIGURE 39.1. Genome and subgenomic transcript map of BDV. S1 through S3, transcriptional initiation sites; T1 through T4, and t6, transcriptional termination sites; ESS, exon-splicing suppressor. Dashed lines indicate readthrough at termination sites T2 and T3. See text for details.

similarity to other known viruses is in the conserved signature motifs of RNA-dependent RNA polymerases (RdRp).^{234,235} The closest phylogenetic relations exist to rhabdo- and paramyxoviruses,^{27,44} with the N-terminal half of the L sequence being closer to rhabdoviruses, whereas the C-terminal half is more closely related to paramyxoviruses.

Sequences distantly related to BDV L, M, and N sequences were recently identified in the genomes of several animal species, including bats, elephants, fish, lemurs, rodents, squirrels, primates, and man.^{11,133} Detailed phylogenetic analyses suggest multiple ancient independent integration events. An intriguing example is a BDV N-related sequence that likely integrated before the separation of marmosets and macaques 40 million years ago.^{11,133} In some instances, the endogenous Borna-like (EBL) element comprises a complete ORF that includes BDV-like transcription initiation and termination signals. The finding of mRNA transcripts of such EBL elements suggests potential functional roles that may include protection from BDV infection.^{11,81}

Genetic Diversity

BDV isolates reveal a remarkably high degree of genetic stability and homology. Among wild-type and experimentally host-adapted viruses, sequence identity is about 95% at the nucleotide level, and 1.5% to 3% at the predicted amino acid level.^{18,27,44,123,161,208,230,278,310} Phylogenetic analysis of wild-type and laboratory strains of BDV indicates distinct clusters, which correspond to the different endemic areas in Central Europe.¹⁶¹ Geographical virus clusters exhibited a higher degree of identity to each other than to BDV isolates from distant regions, independent of host species or year of isolation. There is only one highly divergent BDV strain, No/98, which originated from Styria in Austria where Borna disease is not endemic.²⁰⁸

ABV displays remarkable genetic variability in contrast to the high genome conservation of BDV. At present, 7 different genotypes (ABV1, ABV2, ABV3, ABV4, ABV5, ABV6, ABV of canaries) have been identified that share less than 70% sequence identity to any of the described BDV isolates.^{131,152,217,340,343} The ABV genotypes vary considerably in their gene sequences with

a homology range of 50% to 90% without clustering according to country of origin or avian species.^{131,132,152,153,259,309,340,343} ABV4 appears to be the most abundant genotype in natural PDD cases but also in healthy carriers. Recently, a distinct ABV genotype has been detected in wild geese and trumpeter swans.^{55,217}

Proteins

Nucleocapsid Protein (N)

In BDV, N exists as a 40-kDa and 38-kDa isoform;^{26,156,245} N isoforms have not yet been observed in ABV.^{92,327,328} The 40-kDa variant (p40) is derived from the full length ORF, while the 38-kDa variant (p38) initiates at a second in-frame AUG, resulting in the lack of 13 aa at the amino terminus (Fig. 39.2). Although an RNA with coding information for p38 has been found that starts downstream of S1,²⁴⁵ it is unknown whether p40 and p38 can both be translated from mRNA transcripts starting at the S1 transcriptional initiation site. The 13 aa amino terminal sequence present in p40 contains a nuclear localization signal (NLS; P₃KRRLVDDA₁₁) compatible with the differential cellular distribution of the two isoforms seen in cells transfected with constructs expressing only one of the isoforms; while p40 is primarily nuclear, p38 is primarily cytoplasmic.^{156,245} However, both, p38 and p40 bind to P. As P contains potent NLS (Fig. 39.2), the *in vivo* significance of the two N isoforms is unknown; p38 may enter the nucleus through

interaction with P. Experimental evidence with expression constructs indicates that p38 can accumulate in the nucleus to levels similar to those of p40; however, p38 alone cannot support transcription/replication of BDV (mini-)genomes.²²⁰ Thus, the amino terminal sequence of p40 may have functions in addition to N protein translocation. Both p40 and p38 bind to P through two motifs (K₅₁–Y₁₀₀, and L₁₃₁–I₁₅₈; Fig. 39.2).^{13,155} p38 appears to regulate cellular levels of free p40 by blocking the respective binding site on P, thus modulating cellular ratios of free p40 to P.²⁸⁴ In addition, p38 and p40 contain a nuclear export signal (NES; L₁₂₈TELEISSIFSHCC₁₄₁)¹⁵⁵ that overlaps the binding motif for P (Fig. 39.2). It is therefore hypothesized that p38, which lacks the NLS motif, may redistribute to the cytosol after dissociation from bound P, possibly once assembled in ribonucleoprotein (RNP) complexes.¹⁵⁵ As indicated by purification experiments and co-localization studies, both p38 and p40, as well as P and M, are included with genomic RNA in the RNP.^{35,189} Association of genomic RNA with N relies on basic amino acid residues located in a cleft formed between the amino- and carboxy-terminal helical domains of N.^{129,267} However, binding to N in the multimeric RNP appears not to shield the genomic RNA from enzymatic attack.

Together with P, N constitutes the BDV s-antigen, a complex found in the noninfectious supernatant fluid obtained after high-speed centrifugation of sonicated infected brain tissue or cultured cells. Characterization of the s-antigen provided the

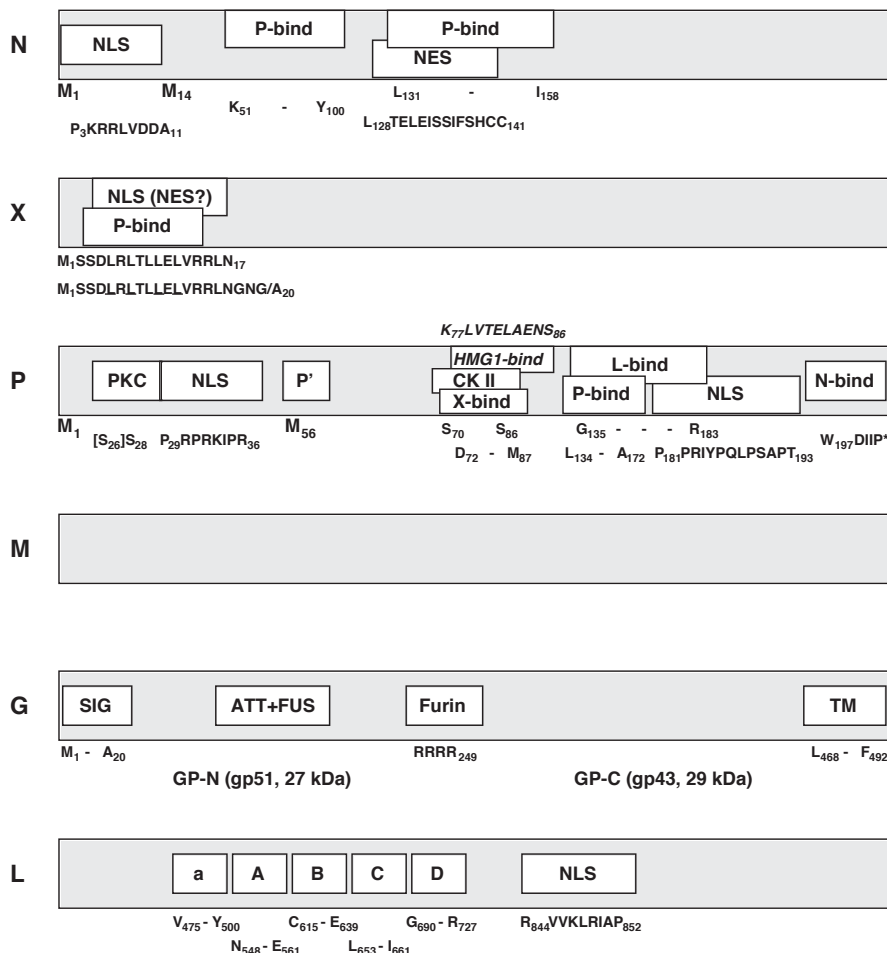

FIGURE 39.2. Map of motifs identified in BDV proteins. See text for further details.

first evidence of protein-protein interactions,^{8,96,177} and until the development of molecular assays, served as the critical diagnostic marker for infection.^{211,332,333}

X Protein (X)

BDV X or p10³³⁹ is a nonstructural protein^{189,288} that, together with P, modulates BDV polymerase activity as a function of the relative abundance of the two proteins.^{237,288} X effects appear to be differently pronounced in different cell types.³⁵³ Although X is not essential for the formation of infectious particles,²¹⁹ it does perform crucial functions during the BDV life cycle because recombinant BDV constructs carrying a nonfunctional X ORF are not viable.²³⁹ Mammalian two-hybrid and co-immunoprecipitation experiments indicate an interaction between X and P,²⁹³ and recombinant BDV systems showed that X inhibited BDV RNA replication and transcription through binding to P^{220,238,285} in the absence of viral M and G.²¹⁹ The site of X interaction with P has been mapped to the N-terminal motif S₃DLRLTLLELVRRRL₁₆, with aa 7 through 15 being probably most essential.^{184,350} X is small (10 kDa) and can be found in the nucleus and cytoplasm. A leucine-rich amino-terminal motif with primary sequence similarity to the NES of cellular and viral export proteins like HIV-1 Rev or PKI (Fig. 39.2, underlined leucines) led to the speculation that X may mediate nucleocytoplasmic shuttling through its interaction with the viral RNP via P. However, X has not been shown to be part of the RNP,^{35,189,219} and other data suggest that this motif functions as an NLS rather than an NES (R₆LTLELVRRNGN₁₉).³⁵¹ These experiments also showed that transport of X through the nuclear pore complex is mediated by direct binding to importin- α .

Phosphoprotein (P)

P, a cofactor of the L viral polymerase, is phosphorylated at multiple serine residues by two different cellular kinases.^{289,320} P is phosphorylated predominantly by protein kinase C ϵ (PKC ϵ) at Ser28 (and Ser26, which is not present in all BDV strains), and to a lesser extent by casein kinase II (CK II) at Ser 70 and Ser 86 (Fig. 39.2). As in other NNS virus phosphoproteins, phosphorylation status may regulate P's ability to form homomultimers, bind to other viral proteins, and serve as a transcriptional activator. P interacts with itself, X, N, M, and L as shown by mammalian two-hybrid and co-immunoprecipitation analyses. Regions of interaction of P with P (aa 135–172), with N (aa 197–201),²⁹³ with M (aa 1–11),³⁵ and with X (aa 72–87)¹⁵⁸ were mapped through analysis of truncation mutants of P. A region of interaction with L (aa 135–183) overlaps that identified for homo-oligomerization; however, the sites are functionally separated as shown by analyses of P mutants that bound to L but had lost the ability to oligomerize.²⁸³ These analyses also demonstrated that P-oligomerization is essential for polymerase activity. Overlap also exists between the CK II phosphorylation sites and the region of interaction with X, as well as between the PKC ϵ phosphorylation site(s) and the amino-terminal NLS of P; two NLS have been mapped at the amino- and carboxyl-terminus of P (Fig. 39.2).^{292,295} Thus, it is conceivable that P phosphorylation may influence nuclear trafficking of P (and possibly of X through its interaction with P). In this context it is intriguing that PKC ϵ is highly concentrated in limbic circuitry,²⁶⁸ as it suggests that PKC ϵ phosphorylation may be important to the limbic distribution of BDV. BDV

infection of neurons interferes with synaptic vesicle recycling through blockade of PKC-phosphorylation of myristoylated alanine-rich C kinase substrate (MARCKS) and mammalian uncoordinated-18 (Munc-18). There is speculation that P may contribute to BDV pathogenesis by competing with neuronal substrates for phosphorylation by PKC.^{241,330}

Matrix Protein (M)

Like the BDV s-antigen, a 14.5-kDa protein purified from infected brain homogenate had been linked to the unidentified BD agent prior to molecular characterization of BDV.²⁷⁴ Once genome sequence data became available, microsequencing indicated that this protein is the product of the 16-kDa ORF of BDV (p16).¹⁵⁴ Subsequent analyses showed that p16 forms noncovalently linked tetramers and constitutes a non-glycosylated viral matrix protein.^{165,166} M is a component of the viral RNP and can bind to P. However, in contrast to other NNS RNA virus M proteins, BDV M appears to have no inhibitory effect on polymerase activity.^{35,189}

Glycoprotein (G)

The BDV glycoprotein is a classical type I membrane protein that is generated from the 57-kDa ORF and posttranslationally modified by N-glycosylation to yield a 94-kDa primary product (gp94).^{252,279} The primary product is processed by cellular furin protease into an amino-terminal GP-N (27 kDa, gp51) and a carboxy-terminal GP-C (29 kDa, gp43) through cleavage after arginine₂₄₉.^{151,252} (Fig. 39.2). Whereas the gp94 precursor contains only high-mannose glycans, analysis of the cleaved fragments indicated glycan maturation by showing mixtures of high-mannose and complex-type glycans on both GP-N and GP-C.¹⁵¹ Anchored by its transmembrane domain, GP-C is transferred to the cell membrane, while the gp94 precursor predominantly accumulates in the endoplasmic reticulum. The final composition of mature virions is not clear; gp94 as well as GP-C and GP-N have been found in infectious particles,^{38,68,84} but GP-N and GP-C were also demonstrated in infectious particles that lacked the gp94 precursor after virus purification.¹⁵¹ Computational analyses indicate an arrangement of structural features of BDV G that is co-linear to rhabdoviral G, suggesting that BDV G also belongs to the class III viral fusion proteins.⁸⁰

RNA-Dependent RNA Polymerase (L)

The large polymerase protein (L) of BDV is the product of alternative splicing, a mechanism unique among NNS RNA viruses.^{27,281} The generated continuous ORF translates a 190-kDa protein³³⁴ that displays motifs characteristic of RNA-dependent RNA polymerases (RdRp). L interacts with P and, analogous to other NNS L-polymerases, it is phosphorylated by cellular kinases (Fig. 39.2).³³⁴ Plasmid constructs directing expression of the continuous 190-kDa protein that supported replication of recombinant BDV genomes confirmed the polymerase activity of the protein.^{187,220,285,286,353} Translocation of L to the nucleus of the infected cell appears to be promoted by an NLS motif (R₈₄₄VVKLRIP₈₅₂; Fig. 39.2) located toward the center of L,³³⁵ or in association with BDV P.²⁸⁵

Cycle of Infection

Attachment and Entry

BDV attachment and entry appear to be analogous to the pH-dependent entry via intracellular vesicles described for

rhabdo- and filoviruses, as opposed to the pH-independent surface fusion mechanism used by paramyxoviruses.^{229,260,269} BDV G binds to one or more still unidentified cellular surface receptor(s).^{84,279} Receptor interaction of G triggers BDV internalization through energy-dependent, clathrin-mediated endocytosis and subsequent pH-dependent membrane fusion leads to release of the RNP from intracellular vesicles into the cytosol.^{37,83} Protease inhibitor studies indicate that cleavage of the precursor gp94 is essential for infectivity.²⁵² Whereas the amino-terminal 244 aa of gp94 and/or GP-N are involved in receptor binding, the hydrophobic amino-terminus of GP-C is hypothesized to initiate membrane fusion upon a conformational change induced by acidification in the early to intermediate endosome.^{37,68,83,221,279} No data are available regarding trafficking of the released nucleocapsid after membrane fusion.

Despite its predilection for neuronal cell types *in vivo*, BDV has the capacity to infect a wide variety of cultured neuronal as well as nonneuronal cell types from many species. Only hematopoietic cells²⁶⁴ and mouse cell lines⁷⁴ have been reported as resistant to infection *in vitro*. This may indicate potential exploitation of secondary receptors, and has also led to hypotheses about a nonreceptor-mediated cell-to-cell spread of BDV that is supported by *in vitro* as well as *in vivo* observations.^{86,180} More recent studies with a CHO cell line that apparently was resistant to infection by BDV virions, and with furin protease-deficient CHO cells, indicated that BDV can disseminate by G-receptor-independent pathways.³⁸ However, correct G maturation enhanced the proposed receptor independent cell-to-cell spread, and is mandatory for the formation of infectious progeny virions.

Transcription, Replication and Gene Expression

Recombinant virus systems confirm that BDV N, P, and L are essential and sufficient for transcription and replication of the viral genome.^{187,219,220,285,286,353} As with other negative-strand RNA viruses, genomic RNA packaged by N constitutes the RNP that serves as a template for the associated polymerase complex components L and P.^{129,189} The BDV X protein, although not part of the incoming RNP complex,^{189,288} appears to modulate the formation and activity of functional polymerase complexes later in infection by buffering the crucial N-to-P ratio and likely attenuating the enzymatic activity of the polymerase.^{219,237,337} Furthermore, BDV is unique among known animal NNS RNA viruses in its nuclear location for transcription and replication.^{24,42} To generate its proteins, BDV uses predominantly polycistronic mRNAs that are transcribed from three transcriptional initiation sites characterized by a CUU consensus sequence and terminate at four AU₆ termination/polyadenylation sites (Fig. 39.1).^{27,276}

The first and second transcription units overlap such that the initiation signal S2 lies upstream of the termination signal T1.^{27,44,240,276} A similar organization was postulated to serve as an attenuation signal for the control of polymerase expression in respiratory syncytial virus.³⁹ However, attenuation appears not to take place in BDV as the two transcription units are found at similar levels,²⁷ in contrast to the usual transcriptional gradient observed in the other viruses of the order. Other factors may modify mRNA levels beyond effects attributable to the typical 3'-to-5' transcriptional gradient, including the incorporation of regulatory sequences in spliced introns.²⁹⁶

Read-through at termination/polyadenylation signals is a vital feature of BDV transcription, leading to primary, sub-genomic RNA transcripts of 0.8, 1.2, 1.9, 2.8, 3.5, and 7.1 kb. The 1.2-kb transcript is the only monocistronic product. It is co-linear with the p40 ORF and directs translation of the p40 and p38 isoforms of BDV N from alternative in-frame AUG codons.^{156,245} The second transcription unit generates the 0.8-kb transcript that codes for the X and the P protein in overlapping ORFs. There is no evidence of splicing to eliminate the AUG initiating translation of X.^{27,276,339} Thus, it is likely that P is expressed through a leaky scanning mechanism, possibly analogous to the termination-mediated reinitiation of X translation from the small upstream ORF included in the 0.8-kb transcript. The expression of X may be further modulated by cellular protein interactions with the long 5'-untranslated region (UTR) of this BDV transcript.³³⁸ The long 5'-UTR region also includes poorly defined regulatory elements controlling polymerase read-through at the T1 signal.^{237,240} Interestingly, the region containing the AUG of the upstream small ORF has been found deleted in sequenced psittacine ABV genomes but not in sequences derived from geese.^{217,259} In BDV, a truncated 16-kDa P' product of undefined function may result from initiation at a downstream in-frame AUG.¹⁵⁷

Read-through at T2 produces an elongated 0.8-kb derivative of 3.5 kb. Two primary transcripts of 2.8 and 7.1 kb are generated from the third transcription unit through differential read-through at T3. The 2.8- and 7.1-kb transcripts include the p16 and p57, or the p16, p57, and pol ORF, respectively; in addition, several secondary transcripts are derived from these RNAs through alternative splicing (Fig. 39.1).

Transcripts of the third transcription unit include two intron sequences, intron-1 and intron-2, that are subject to alternative splicing.²⁸¹ Whereas the 2.8- and 7.1-kb transcripts direct translation of M, the expression of G likely requires removal of intron-1. Although G may also be expressed *in vitro* from unspliced transcripts by leaky ribosomal scanning, splicing of intron-1 creates a stop-codon after the 13th aa of the p16 ORF that facilitates translational initiation at the AUG of G.²⁸⁰ Splicing of intron-2 removes almost the complete p57 ORF and fuses a small 17 nt ORF located upstream of the splice donor site to the large downstream ORF that, in the case of the 2.8-kb RNA, terminates at T3, generating a truncated L protein of unknown function (Fig. 39.1). Expression of L is, analogous to G, likely facilitated by splicing of intron-1. In addition, an alternative splice acceptor site, controlled by a downstream exon-splicing suppressor, has been identified at nt 4559.³²² Splicing of this potential intron-3 (nt 2410–4559), and transcriptional read-through at t6,²⁷ may result in expression of two additional BDV-specified proteins.^{43,322} However, the splice acceptor site at nt 4559 is not strictly conserved throughout sequenced BDV isolates. The lack of conservation in BDV No/98²³⁰ as well as in ABV isolates indicates that the potential gene products are unlikely to fulfill essential functions in the bornavirus life cycle.

There have been reports of multiple types of BDV 1.9-kb RNA transcripts with unspecified function. Analyses based on RNA circularization and sequencing over the junction indicated the presence of a noncapped RNA complementary to position 1 to 1882 of the BDV genome that interacted with oligo(dT)-beads, but was not fully polyadenylated.²⁷⁶ Such transcripts may represent abortive replication intermediates or subgenomic

RNAs analogous to leader RNAs found in other mononegaviruses. On the other hand, studies employing precipitation with a cap-specific antibody characterized a capped 1.9-kb mRNA with a long poly(A)-tail, extending from S1 to T2²⁴⁰ (Fig. 39.1).

Initiation of transcription and replication in negative-strand RNA viruses is commonly mediated by sequences located in the UTR. A single transcriptional promoter located in the 3'-UTR of the genome generates the usual transcriptional gradient, and promoter sequences driving genome replication are located in both the complementary 3'- and 5'-genomic termini. However, BDV analyses indicated remarkable terminal heterogeneity.²³⁰ Kinetic analyses comparing the genomic termini in acute and persistent BDV infection showed an accumulation of terminal truncations in the course of infection, which in several cases resulted in strongly attenuated replicational and transcriptional promoter activity, possibly contributing to BDV's persistent lifestyle.²⁶¹ In addition, rescue of infectious recombinant BDV constructs demonstrated trimmed 5' genomic termini generated from originally perfectly complementary constructs.²⁸⁶ In this system, when recessed 5' ends aligned to the 3' terminus were generated, there was strong attenuation of replication while transcriptional activity appeared to be unaffected. This finding is compatible with the high antigen levels in conjunction with low levels of infectious virus that are observed during persistent BDV infection. The four 5' terminal bases of genome and antigenome appear to be copied from internal template motifs through backfolding of the termini followed by specific elongation and termination on the template motifs.¹⁸⁶ This allows later cleavage of these terminal bases to generate monophosphorylated 5' termini of progeny strands without the loss of genetic information. Trimming of the termini in BDV may support its persistent infection by escape from innate immune responses through RIG-I-mediated recognition of triphosphorylated genomic termini.⁹⁷ It is not known whether viral and/or host functions are responsible for the terminal trimming. Further characterization of these unique BDV transcriptional and replicational promoter sequences may help to resolve results obtained in various recombinant test systems.

Assembly and Release

As with other negative-strand RNA viruses, a first step in the production of BDV progeny is packaging of the replicated nascent genomic RNA by N. The 5'-trailer RNA specifically promotes its association with N via basic residues in the cleft between the amino- and carboxy-terminal domains of the protein.^{129,267} Formation of the RNP complex includes association of P via its carboxy-terminal aa residues, and the inclusion of L is hypothesized to occur via its characterized protein-protein interaction sites (Fig. 39.2). Based on NLS located in N, P, L, and X, and NES in the two N isotypes and possibly X, various hypotheses concerning nucleocytoplasmic shuttling of BDV RNP have been proposed, but experimental confirmation is lacking. Colocalization studies suggest that M is also an integral part of the BDV RNP.³⁵ M, but not X, has been demonstrated in purified RNP,¹⁸⁹ a finding consistent with the observation that in recombinant BDV mini-genome systems the expression of M and G, but not X, is required for the formation of infectious BDV-like particles.²¹⁹ The processing of BDV G by protease digestion appears to be crucial to the assembly of infectious virions.^{5,38} Distinct packaging signals are not defined.

EPIDEMIOLOGY OF BDV INFECTION

Host Range

BD is reported most commonly in horses and sheep; but disease has also been reported in other *Equidae*, farm animals (cattle and goats), rabbits, lynx, zoo animals (alpacas, sloths, various monkeys, hippopotamuses), and rarely in companion animals (dogs and cats).^{21,31,46,54,67,113,138,140,182,192,262,310,344,358} Experimental infections have been achieved in various animal species ranging from chickens to nonhuman primates.^{4,46,87,113,148,188,201,212,255,262,266,308,314} Infection in horses leads to death 1 to 4 weeks after onset of signs in 80% to 90% of animals.^{67,89,91,253} In 72% of stables with equine BD cases, only individual animals develop clinically manifested BD. In cattle and sheep, death was noted after 1 to 6 weeks or 1 to 3 weeks in more than 50% of animals, respectively.^{21,255}

Geographic Distribution and Potential Reservoir

Natural BD is endemic in areas of central Europe such as southern and eastern Germany, Switzerland, Liechtenstein, and Austria.^{30,46,66,113,120,193,344,358} Reports of natural BD outside these endemic areas suggest a wider distribution of the disease.^{78,98,99,144,147,178,253,262,354} Virus-specific serum antibodies and/or nucleic acids in absence of disease or in association with unusual clinical signs have been reported in animals from different geographic areas, including European countries, such as France, Sweden, Finland, and Italy, as well as Turkey, Israel, Japan, Iran, China, Australia, and the United States.^{66,78,98,99,144,147,178,253,262,354} However, as some of these data are debated and require more confirmation, further epidemiologic studies are warranted.

A seasonal accumulation of BD cases in April, May, and June—with a significant decrease in late fall and winter—is quite characteristic and argues, in combination with the geographically limited occurrence, for a natural reservoir.^{66,67,89,113,181,325} Recently, BDV infection has been detected in bicolored shrews (*Crocidura leucodon*) in endemic areas in Switzerland. These animals had a disseminated virus distribution in the absence of overt disease and represent a potential reservoir for BDV.^{127,244} Whether other species can serve as reservoir species is currently unknown.

Prevalence and Seroepidemiology

In contrast to the epidemic course of BD at the end of the 19th century, the incidence of BD decreased significantly during recent decades; usually less than 100 horses or sheep are diagnosed with BD per year.^{66,120,199} However, BDV infections in horses and sheep can be inapparent as indicated by seroepidemiologic surveys in Germany. The average seroprevalence of BDV-specific antibodies in clinically healthy horses in Germany is approximately 11.5%¹²⁰ and increases in endemic areas up to 22.5%, reaching 50% in stables with a history of clinical BD.⁹¹ There is a higher frequency of BD on farms with mixed stock of horse, sheep, and cattle, operating under lower hygiene standards.⁶⁶ Repeated outbreaks of BD within the same premises have been noted but usually spaced several months or years apart.^{91,253} The reason for the discrepancy between the high BDV seroprevalence and the low BD incidence remains unknown but may relate to age, immune status, genetic background, virus strain, and/or dose of infection.

Route of Infection and Transmission

There is evidence that nerve endings in the nasal and pharyngeal mucosa represent the most likely natural route of entry.^{142,188,197} Experimental BDV infection of neonatal rats results in virus persistence and disseminated virus distribution with presence of viral gene products and infectious virus in saliva, urine, and feces.^{188,197} Such secretions or excreta are important in transmission of other pathogenic viruses (e.g., lymphocytic choriomeningitis virus and hantaviruses). This finding further supports the concept of a natural reservoir of BDV, which is substantiated by stable geographic virus clusters,^{18,161,325} despite substantial horse movement and trade. This was recently confirmed by a case of natural BD in Great Britain that was traced back to a likely origin of infection in Germany.²⁴² It seems that widespread horse-to-horse or sheep-to-sheep transmissions do not occur.^{16,66,254,310} The infectious dose for natural infections is unknown.

EPIDEMIOLOGY OF ABV INFECTION

The epidemiology of ABV infections is less well understood. Since its first description in the United States and Israel in 2008, ABV infections have been reported from various European countries, for example, Germany, Austria, Switzerland, Hungary, Spain, Italy, United Kingdom, and Denmark, but also from Canada, Australia, and Japan,^{112,131,152,172,209,246,259,340} indicating a worldwide distribution of ABV.

Within the order *Psittaciformes*, ABV infections have been reported in captive psittacines of 34 different genera as well as in a canary (*Serinus canaria*), and recently in a toco toucan (*Ramphastos toco*) and wild waterfowl (Canada geese, [*Branta canadensis*], and trumpeter swans, [*Cygnus buccinator*]) in Canada and the United States.^{55,112,132,218,343} Whether wild birds might serve as a natural reservoir for ABV remains to be further investigated. The transmissibility of ABV in natural infections has also been confirmed.^{111,153} The natural route of ABV infection is unclear but detection of ABV RNA in feces, cloacal and crop swabs argues for oronasal entry and bird-to-bird transmission. The possibility of vertical transmission has to be further investigated.¹⁷³

HUMAN INFECTION

Much of the impetus for characterization of BDV came from concerns that it infected humans and might be implicated in psychiatric syndromes, including major depressive disorder, bipolar disorder, schizophrenia, and autism, as well as chronic fatigue syndrome, AIDS encephalopathy, multiple sclerosis, motor neuron disease, and brain tumors (glioblastoma multiforme) (Tables 39.1 and 39.2). Over a period of three decades investigators reported evidence for human infection using primarily PCR and serologic assays, including the detection of circulating immune complexes.²³ However, there were also reports of infectious virus isolated from humans or BDV gene products detected in human brain by *in situ* hybridization and immunohistochemistry.^{53,202} Failure to independently replicate positive results in the majority of laboratories undermined confidence in the association of BDV with human disease.^{175,349} Another concern was the possibility of cross-contamination suggested

by sequence similarity of putative human BDV sequences with those of the laboratory strains and field isolates handled in the laboratories reporting the human sequences.^{65,134,250,291,310,349} A recent blinded multicenter analysis failed to find either molecular or serologic evidence for human BDV infection using methods established by investigators reporting links between BDV and human neuropsychiatric disease.¹³⁴ Thus, although the potential for human infection has not been excluded it is exceedingly unlikely that a bornavirus similar to those identified to date is responsible for a significant burden of human disease.

BDV NEUROPATHOGENESIS

Experimental Infection of Animals with BDV

Early virus detection and isolation experiments by Zwick and colleagues were performed in rabbits,³⁵⁸ which has served since then as the most sensitive small-animal model for BDV infection. Rabbits are highly susceptible and after early weight loss develop neurologic disease about 3 weeks after infection with BDV-infected brain homogenates. Symptoms include slow movement, depression, and somnolence followed by flaccid back musculature, paresis starting from the hind limbs, and trismus.¹⁷⁹ Comparable to BD in ungulates, infection of rabbits is not characterized by excessive hyperactivity, as seen in infected rats. Nevertheless, most insights into pathogenesis have been obtained after adaptation of BDV to the rat.^{128,203,204,206} Susceptibility to disease in rats is genetically determined. Wistar rats and black-hooded rats show less severe disease than Lewis rats, a strain with deficiencies in the hypothalamic–pituitary–adrenal axis associated with enhanced susceptibility to immune-mediated disorders.^{36,128,312} Resistance to BD is inherited as a dominant trait independent of MHC genes in black-hooded and Lewis hybrids.^{121,128} Serial passage in rat brain may enhance the virulence of BDV strains for rats.²⁰⁶ BDV infection of susceptible adult rats results in a biphasic disorder that manifests approximately 10 to 20 days after intracerebral infection as an acute immunopathologic disease, presenting clinically as hyperactivity and exaggerated startle responses.^{203,204} The onset of acute disease coincides with infiltration of mononuclear cells into the brain, particularly in areas of high viral burden such as the hippocampus, amygdala, and other limbic structures.³² After the initial acute phase, the animals enter a chronic disease phase characterized by somnolence, apathy, paralysis, dystonias, dyskinesias, stereotyped and self-mutilation behaviors, and blindness.^{203,204,299,301} Chronic disease is paralleled by widespread distribution of virus in the limbic system and prefrontal cortex, and 5% to 10% of animals become obese, developing up to 3 times the weight of normal rats.¹⁷⁹ BDV variant strains have been described that cause primarily an obesity syndrome without obvious neurologic disease. The obese phenotype is correlated with inflammation and viral antigen expression in the septum, hippocampus, amygdala, and ventromedian tuberal hypothalamus.¹¹⁶

Initially, the unique neuropathogenesis of BDV was mostly studied in the adult rat model, in which infection is associated with behavioral changes and disturbances in monoamine neurotransmitter systems and limbic circuitry. However, disease in immunocompetent adults is characterized by marked CNS inflammation, loss of brain mass, and gliosis. In contrast, neonatally infected rats present with hippocampal and cerebellar

dysgenesis and display behavioral changes in the absence of appreciable inflammation, which offers an alternative, potentially more relevant model to study consequences of viral infection of the CNS. Rats inoculated as neonates with low passage virus during the first day of life become persistently infected, are smaller than uninfected littermates, and display only mild behavioral disturbances manifest as cognitive, emotional or social deficits.^{10,33,61,135,169,231,232,265}

In addition to rats, BDV has been experimentally transmitted to a variety of other animal species. Susceptibility to infection varies according to species and virus strain. Compared to the highly susceptible rabbits, guinea pigs, gerbils, and rats, other species, such as mice, cattle, chickens, monkeys, and tree shrews, appear to be less susceptible to disease.^{4,46,87,148,179,188,201,255,262,266,308,314}

Ferrets, pigeons, dogs, and hamsters develop no disease symptoms although they usually become persistently infected.^{46,262}

BDV Infection of the Adult Rat

Intracranial, intraocular, or intranasal inoculation routes have been used to infect adult rats. However, all routes that give the virus access to nerve terminals appear successful and produce infection of the CNS and symptomatic disease after varying incubation periods. Onset of disease correlates with distance from the inoculation site to the CNS,³² indicating that BDV spreads primarily through neural networks. This is supported by the finding that sciatic nerve transection after footpad infection prevents CNS infection.³² Further, after olfactory, ophthalmic, or intraperitoneal inoculation, viral proteins or nucleic

acids move centripetally via synaptic connections.³² Analogous to rabies virus, spread of viral RNPs instead of mature virus within neural networks has been hypothesized for BDV⁸⁶; and the possibility of G-receptor-independent dissemination of BDV has been described *in vitro*.^{38,180} Although viral RNA can be found in peripheral blood mononuclear cells (PBMC) of infected animals, viremia is currently not considered to play a significant role in the pathogenesis and dissemination of BDV.

BDV infection of adult Lewis rats results in severe CNS immunopathology and pronounced behavioral disturbances.^{203,204,257,313} Monocyte infiltration, glial activation and Th₁-type cytokines in limbic structures coincide with the onset

of hyperactivity and exaggerated startle responses 2–3 weeks after infection and persist until the animals enter the chronic phase approximately 12 weeks later. This is associated with a switch of the Th1 to a Th2 response.¹⁰⁴ Microglial activation precedes astroglial reaction but seems to depend on persistent infection of neurons and activation of astrocytes.^{118,214} In many other viral CNS infections, the presence of an intact immune response results in viral clearance or death of the host. However, in BDV infection the virus persists at high titer in the presence of a robust cellular immune response during the acute phase, and also during the chronic phase when Th₂-type cytokines increase while immune cell infiltrates decline in the

presence of almost unchanged viral load in the CNS and continued glial activation.¹⁰⁴ While lymphocytes isolated from the brains of acutely infected rats had potent cytolytic activity *in vitro* and can recreate BDV-specific pathology after adoptive transfer into healthy, immunosuppressed BDV-infected rats, the lymphocytes isolated from brains of chronically infected rats failed to lyse BDV-infected target cells *in vitro* or to induce pathology after adoptive transfer.²⁹⁷ Furthermore, levels of IgG antibodies produced intrathecally increase during the chronic disease phase, accompanied by high titer neutralizing antibodies in peripheral blood,^{105,106} in addition to the nonneutralizing anti-N and anti-P serum antibodies generated during the acute phase.^{25,77} Although the increasing titer of neutralizing antibodies does not result in viral clearance, it is likely restricting the virus to the nervous system. Passive immunization of immunoincompetent rats restricts viral replication to cells of the central, peripheral, and autonomic nervous system, whereas rats not passively immunized showed viral replication outside of the nervous system.³¹⁵

Infection of immunoincompetent, immunosuppressed, or athymic animals does not result in overt disease, and combined with the fact that BDV does not show cytopathic effects in cultured cells suggested a primarily immune-mediated pathology in immunocompetent adult rats.^{125,203,204,318} This was further supported by the finding that adoptive transfer of spleen cells from diseased rats, or of BDV-specific CD4⁺ T-cell lines, triggered classical disease in such animals.^{203,226,249,256,257,297} Infiltrating cells in infected animals include CD4⁺ and CD8⁺ T cells, macrophages and B cells, with CD4⁺ cells accumulating primarily in perivascular cuffs and CD8⁺ cells distributing in the parenchyma.^{17,57,225} A crucial role for CD8⁺ cells has been deduced from the effects of antibody treatment against CD4⁺ and CD8⁺ cells, which led in both cases to neuroprotection and abrogation of severe immunopathology.^{17,226,317} However, the ultimate mechanisms of immune-mediated pathologic cell death remain undefined. Both CD4⁺ cell lines possessing or lacking cytotoxic capacity have been established, and although current evidence is compatible with an involvement of classical cytotoxic T-cell action,²⁰⁷ a role of indirect mechanisms elaborated through proinflammatory cytokines and their potentially cytotoxic effects, particularly in neuronal cell death, is also possible.²¹⁵ The immunopathology in adult infected rats represents a delayed-type hypersensitivity response with contribution of both CD8⁺ and CD4⁺ T cells in the immunopathologic events.

Behavioral and movement disturbances in adult infected rats have been linked to dysfunction of the dopamine (DA) neurotransmitter system.^{299,300,301–302,303} Both pre- and postsynaptic sites appear to be damaged. DA reuptake sites are reduced in the caudate-putamen and nucleus accumbens.^{302,303} DA receptor losses vary by receptor subtype and brain region. D2-receptor binding is markedly reduced in the caudate-putamen. Both D2 and D3 receptor binding are reduced in nucleus accumbens.^{300,301–302} In contrast, postsynaptic DA receptors (D1, D2, D3) are intact in the prefrontal cortex.³⁰⁰ Selective losses of D2 receptors and resultant D1 receptor hypersensitivity may be implicated in behavioral disturbances. Whereas treatment with D1 receptor antagonists such as SCH23390, or clozapine—an atypical antipsychotic with mixed D1, D2, D3 and D4 antagonist activity—reduces repetitive and self-injurious behaviors, D2-selective antagonists such as raclopride do not.³⁰¹ Neuro-

chemical studies indicate a lesion in DA transmission consistent with partial DA deafferentation and compensatory metabolic hyperactivity in nigrostriatal and mesolimbic DA systems.

In addition to disturbances in the DA system, decreased mRNA levels for somatostatin, cholecystokinin, and glutamic acid decarboxylase have been recorded in adult infected rats during the acute phase of disease, while recovery to normal levels was observed during the chronic phase.¹⁷⁴ Decreases are also evident in choline acetyltransferase-positive fibers of the cholinergic system involved in learning and memory. Losses in cholinergic fibers become evident by 6 days postinfection (dpi), and almost complete absence of choline acetyltransferase-positive fibers is reported in the hippocampus and neocortex by 15 dpi.⁸² Infected animals also respond abnormally to the opiate antagonist naloxone with hyperkinesia and seizures.³⁰⁵ Normal rats show increased levels of the endogenous cannabinoid anandamide in hippocampus and amygdala after naloxone treatment, and develop no seizures. In virus-infected rats seizures develop after naloxone treatment, while anandamide levels remain comparable to baseline levels recorded in the same structures of mock-treated BDV-infected or normal rats.²⁹⁸ Blockade of anandamide transport in infected rats prevented naloxone-induced seizures. Furthermore, levels of mRNA encoding the opioid precursor preproenkephalin were elevated in striatum of infected rats 14, 21, and 45 dpi, and virus and met-enkephalin co-localized in a high percentage of cells.^{75,304} Induction of enkephalin expression in infected cells may relate to increased levels of phosphorylated cyclic AMP response element binding (phosphoCREB) protein due to activation of the mitogen-activated protein kinase (MAPK) pathway.¹⁶² Indeed, interaction of BDV with MAPK signaling has been demonstrated in cell culture systems.^{103,227} The marked CNS inflammation in adult infected rats makes it difficult to determine to what extent monoamine, cholinergic, and opiateergic dysfunction results from direct effects of the virus, indirect effects on resident cells of the CNS, or cellular immune responses to viral gene products.

BDV Infection of the Neonatal Rat

The neonatal rat model is not characterized by overt immunopathology as described for the adult rat; instead, lifelong persistence of high virus load in the brain correlates with only mild behavioral disturbances that are compatible with the observed cerebellar and hippocampal dysgenesis.^{33,136,204} Infected animals exhibit learning deficits, increased motor activity, decreased anxiety responses, stereotypic behaviors, reduced initiation of and response to play interactions, and a preference for salt solutions.^{10,61,136,233,265} Compared to normal littermates, rats neonatally infected with BDV show an altered circadian rhythm, and have a smaller size, although food ingestion and levels of glucose, growth hormone, and insulin-like growth factor 1 appear to remain at normal levels.^{9,10,33} Neuropathologic, physiologic, and neurobehavioral features of the neonatal BDV infection are therefore suitable for exploring the mechanisms by which viral and immune factors may damage developing neurocircuitry.

Despite significant astrocytosis and microgliosis, the overall CNS architecture of neonatally infected rats appears maintained, although losses in distinct structures such as the granule cells of the dentate gyrus after formation of mossy fibers, Purkinje cell subsets of the cerebellum in a temporal pattern, and pyramidal

neurons of the cortex, are recorded.^{69,136,265,290,342,346,347} Consistent with Purkinje cell loss in the cerebellum, testing of cerebellar function demonstrated deficits in motor coordination and postural stability.¹³⁶ Neuronal loss in the dentate gyrus correlates with the severity of the spatial learning and memory deficiencies observed.^{231,265}

BDV infection in neonates does not cause immunopathology, but transient and modest immune responses are observed. Serum antibody titers measured in an immunofluorescence assay are low in comparison to adult infected rats, but persist for more than 10 months.³³ In the CNS a brief surge of T-cell infiltration is observed starting at 4 weeks and resolving by 6 weeks postinfection, paralleled by elevated expression of proinflammatory cytokine, chemokine, and chemokine receptor transcripts,^{136,248,271,272,357} whereas the observed neuropathology parallels regions and time course of microglial proliferation and expression of MHC class I and class II, ICAM, CD4 and CD8 molecules.³⁴²

Abnormal regulation of apoptosis also contributes to the disturbance of CNS architecture in neonatal BDV infection. Excitotoxic stimulation, including activation of glutamatergic circuitry, is one factor that might trigger neuronal apoptosis. There are complex alterations in mRNAs for apoptosis mediators in the hippocampus, amygdala, prefrontal cortex, nucleus accumbens, and cerebellum consistent with prolonged promotion of apoptosis throughout the brains of rats neonatally infected with BDV.¹³⁶ Levels of mRNAs for FAS and ICE (caspase-1), two promoters of apoptosis, were increased. Levels of mRNA for bcl-x, a factor that inhibits apoptosis, were decreased. Maximal shifts were observed at 4 and 6 weeks postinfection, closely paralleling the increases in proinflammatory cytokines noted earlier. Terminal deoxynucleotidyl transferase dUTP-biotin nick end labeling (TUNEL) was shown in cerebral cortex and dentate gyrus, and in the granule cell layer of the cerebellum.^{136,342} Degeneration of cells in the hippocampal formation is related to activation of caspase 3, PARP-1, and deregulation of zinc homeostasis.³⁴⁶ Although apoptosis is described in the normally developing rat hippocampus as late as days 7 to 10 of postnatal life, it is normally not found at later time points.³²³ The anatomic location of apoptotic cells and the absence of inflammatory cells in the hippocampus and cerebellum suggest that apoptotic processes may play a more important role than cell-mediated immunity to BDV in neonatal BDV infections.

CNS dysfunction in neonatally infected animals may be linked to direct viral effects on morphogenesis of the hippocampus and cerebellum, two structures that continue to mature postnatally in rodents. BDV-induced down-regulation of the neuronal gap junction protein connexin 36 occurs first throughout the hippocampal formation and at 8 weeks postinfection also in the cerebellum; this indicates reduced electrical coupling and impaired neuronal functioning in these structures.¹⁶³ Further studies are needed to evaluate the mechanisms by which early postnatal exposure to BDV induces apoptotic losses and morphogenic damage in cerebellar and limbic circuitry.

BDV Infection of Tree Shrews

Nonacute infection in a phylogenetically higher species has been reported in the prosimian tree shrew (*Tupaia glis*). In this model, intracerebral inoculation establishes a persistent infection and

transient mild encephalitis, resulting in a disorder characterized primarily by hyperactivity and alterations in sociosexual behavior rather than motor dysfunction.³⁰⁸ Housing of animals as mating pairs revealed pronounced disturbances in social and breeding behavior.³⁰⁸ Females, not males, initiated mating and despite increased sexual activity the infected animals failed to reproduce. The behavioral changes were attributed to dysfunction of the limbic system, although neuroanatomic analyses were not performed.

BDV Infection of Nonhuman Primates

The only reported studies of experimentally infected primates employed adult immunocompetent rhesus macaques (*Macaca mulatta*). Following intracerebral infection, an acute neurologic syndrome ensued, during which animals were initially hyperactive and subsequently became apathetic and hypokinetic, similar to BDV-infected adult rats. Pathologic changes were remarkable and severe meningoencephalitis and retinopathy were observed.^{34,205,223,314,358}

BDV Infection of Mice

Adult mice develop high virus titers in the CNS after BDV inoculation, but most strains do not develop encephalitis.¹⁴⁸ However, disease may be induced by infection of certain mouse strains during the neonatal period¹⁰⁰ or by adaptation of virus through multiple passages in mice.²⁶⁶ Serial passage results in adaptive mutations in the viral polymerase that may contribute to pathogenicity.² The reason for the different course of experimental BDV infection in adult vs. newborn mice, and in rats, remains unclear, but might be associated with the time point of antigen presentation in the periphery.¹⁰⁷

The incidence and severity of BDV-induced clinical manifestations varies considerably between different mouse strains. Similar to the adult rat model, occurrence of clinical signs is associated with immune cell infiltration in the brain and glial activation, mainly in the cerebral cortex and hippocampus. An immunopathologic syndrome mediated by MHC class I-restricted CD8⁺ T cells in a CD4⁺ T-cell-dependent manner is most pronounced in mouse strains such as MRL with the MHC H-2k allele.^{100,108} This MHC I-haplotype is associated with severity of clinical disease, but the incidence of disease is most likely associated with other, to date unknown, genetic factors.¹⁰⁰ The BDV N peptide T₁₂₉ELEISSI was the dominant epitope shown to sensitize cytotoxic T cells.²⁷⁵ Transgenic expression of BDV-N in neurons or astrocytes in B10.BR mice did not result in clinical disease and prevented induction of BDV-N specific CD8⁺ T-cells.²⁴⁷ Moreover, downregulation of the functional avidity of virus-specific CD8⁺ T cells in experimentally infected mice seemed to be involved in controlling the inflammatory reaction and facilitating viral persistence.⁷¹ Overexpression of cytokines such as IL-12 or TNF in mice less susceptible to BDV-induced disease sensitize the mice to develop an immune-mediated disorder and clinical disease, for example, epileptic seizures in the case of TNF overexpression.^{73,100,130,164} The IL-12 effect seems to be mediated via IFN- γ , which also exerts neuroprotective effects in the mouse model.^{109,130}

A behavioral syndrome similar to that of neonatally infected rats has been described after expression of an individual BDV gene product in transgenic mice. High glial expression of BDV-P decreases synaptic density, serotonin receptors, and levels of brain-derived neurotrophic factor (BDNF), resulting

in behavioral disturbances.¹⁴⁵ Thus, at least one viral product interferes with neural function (see below), but in natural disease, replication of the virus itself and other viral components are also likely to contribute.²³⁶

Tissue Culture Models

Studies in cell culture systems are beginning to provide further insights into the mechanisms by which BDV interferes with cellular functions and induces neuropathology. Interference with basic cellular signalling pathways and modulation of cellular protein functions through direct binding by, or indirect interaction with, individual viral proteins has been recognized. The N-terminal portion (aa 13–171) of BDV N binds to the Cdc2-cyclin B1 complex and delays cell cycle progression in primary rat and mouse fibroblasts.²²⁸ Direct protein-protein interaction was also shown between BDV P and the neurite outgrowth factor amphoterin (also designated HMG1).¹⁴⁶ Complex formation between amphoterin's A-box and BDV P (aa 77–86) leads to competitive inhibition of p53 binding to amphoterin, resulting in downregulation of cyclin G promoter activity.³⁵⁵ Through interference with the transcriptional activity of p53, BDV may affect cell-cycle regulation as well as apoptosis. BDV P interaction with amphoterin also causes altered intracellular distribution of amphoterin in infected cells, leading to an inhibition of neurite outgrowth and migration that has been ascribed to interference with the normal interaction between amphoterin and its receptor RAGE (Receptor for Advanced Glycation End-products).¹⁴⁶ Studies of neuronal differentiation of PC12 cells indicate an interaction of BDV with cellular MAPK signaling pathways.¹⁰³ Persistently infected PC12 cells demonstrate constitutive phosphorylation of MAPK/ERK kinase (MEK), extracellular signal-regulated kinase (ERK), and the E 26 (ETS)-like transcription factor 1 (Elk-1); however, nuclear translocation of ERK is impaired, contributing to the failure of the cells to differentiate with nerve growth factor (NGF) treatment. Activation of MAPK signaling is evident within 1 hour after acute infection, suggesting that gene expression is not required for BDV's activation of the MAPK cascade, whereas sustained MAPK activation appears essential to virus transmission. Chemical blockade of MEK inhibited virus spread to neighboring cells.²²⁷ BDV impairment of ERK-mediated neurotrophin signaling also modulates synaptic functioning by interfering with synaptogenesis and synaptic protein synthesis.¹⁰² Analogous to findings in the neonatal rat,⁸⁵ BDV infection of neuronal cells specifically downregulates the expression of proteins related to synaptic plasticity, such as synaptophysin and growth-associated protein 43 (GAP-43).¹⁰³ In addition, infection interfered with synaptic activity by inhibiting synaptic vesicle recycling in response to stimulus-induced potentiation in hippocampal neuronal cultures.³³⁰ Several cellular kinases participate in the phosphorylation events involved in synaptic vesicle recycling, including protein kinase C (PKC), the epsilon isoform of which phosphorylates BDV P.²⁸⁹ Thus, it is conceivable that the high levels of BDV P that are expressed in the cytoplasm as well as in the nucleus of BDV-infected cells may act as a decoy substrate for PKC, analogous to the BDV P phosphorylation by Traf family member-associated NF- κ B (TANK)-binding kinase 1 (TBK-1) that results in the suppression of TBK-1-dependent interferon (IFN) expression in non-neuronal cells.³²⁴ However, species-specific differences appear to exist in the susceptibility of BDV to the antiviral action of

IFN γ . Human IFN γ efficiently prevented BDV infection of human and monkey cell lines, whereas rat IFN interfered only ineffectively with the infection of rat cell lines or rat hippocampal slice cultures.²⁷³ Moreover, experiments in mouse brain slice cultures indicated a tissue-specific action of IFN γ , with a more pronounced effect of IFN γ on BDV proliferation in cerebellar than in hippocampal cultures.⁷⁴

NATURAL INFECTION WITH BDV

Clinical Signs

In the main natural hosts, horse and sheep, infection with BDV typically causes a severe neurologic disorder.^{29,30,67,89,91,113,139,179,181,193,253,262} Death within 1 to 4 weeks after onset of clinical signs is common. However, inapparent infections occur more frequently in both horses and sheep.^{120,199,253} Clinical recovery or recurrence of acute disease is observed only rarely.^{46,67,89,91,113,149,190,193,223,253} A few animals may also develop a chronic disease course with low-level viral persistence. The incubation period for natural BD has been estimated to range from 2 weeks to several months.^{181,262} This is substantiated by recent cases of natural BD in a horse in the United Kingdom and an alpaca in Germany that had likely been infected in their endemic home areas before transport to the new housing areas outside endemic regions, where clinical signs were noted approximately 3 to 4 months later.^{140,242} In experimental studies, the incubation period for 3 ponies after intracerebral inoculation was 15 to 26 days.¹⁴⁹

Neurologic signs of BD in horses may vary between individual animals depending on the brain area affected by inflammatory lesions and on the course of the disease (Fig. 39.3).^{67,89,91,181,253,358} Clinical hallmarks are simultaneous or consecutive changes in psyche, sensorium, sensibility, motility, and in the autonomous nervous system.^{67,89,91,113,181,253,262,358,361} Recurrent therapy-resistant fever, lethargy, somnolence and stupor, hyperexcitability, fearfulness, and aggressiveness accompanied by repetitive motor activities, slow-motion eating, and “Pfeifenrauchen” (pipe smoking, eating arrest with chewing movements, Fig. 39.3A) are typically recorded. Disturbances of mental status could be attributed to impairment of the limbic system, mainly the hippocampus, which usually shows the most pronounced inflammatory lesions.^{15,89,91,117,253} With disease progression, postural instability, unawareness, hyporeflexia, hypokinesia, head tilt, hypoesthesia with disturbances in proprioceptive sensory functions, and ataxia can appear (Fig. 39.3B). Finally, food intake ceases; torticollis, compulsive circular walking, head tremor with subsequent convulsions and head pressing, coma, and possibly blindness are characteristic (Fig. 39.3C).^{15,91,126} Depending on brain inflammation localization, cranial nerve disturbances might lead to dysphagia, salivation, trismus, and facial nerve paresis, as well as nystagmus, strabismus, or miosis.^{91,253} Besides neurologic signs, a variety of atypical symptoms have been reported, for example, mental, behavioral or gait disturbances, recurrent colic, emaciation, and chronic lameness.^{12,22,58,66,178}

Sheep can develop similar clinical signs as horses, with disturbances in behavior and movement.³⁰ The few cases of natural BD in cattle exhibited a classical neurologic disorder analogous to horses.^{21,31} Rabbits, analogous to experimental

FIGURE 39.3. Clinical signs of Borna disease in horses in different stages of disease. **A:** Early stage of BD. The BDV-infected horse exhibits somnolence and eating arrest with chewing movements (so-called “Pfeifenrauchen” or “pipe smoking”). **B:** More advanced stage of BD. The BDV-infected horse displays abnormal posture as sign of disturbed proprioception and facial nerve paralysis. **C:** Final stage of BD. The BDV-infected horse presents neurogenic torticollis and compulsive circular walking. (From Richt JA, Grabner A, Herzog S, et al. Borna disease in horses. *Vet Clin North Am Equine Pract* 2000;16:579–595, with permission.)

infection, develop an acute and fatal paralytic disease accompanied by blindness.^{181,192,212,262}

Pathogenesis

In horses, gross findings are mostly sparse and consist of leptomeningeal hyperemia, brain edema, or hydrocephalus internus in later disease stages.^{113,149,358,361} Viral antigen and RNA are present in neurons, astrocytes, and occasionally in ependymal cells and oligodendrocytes as described for experimental infections of rodents (Fig. 39.4). In contrast to the variability of lesion severity and affected organs in ABV infections (see below), histopathologic changes after BDV infection are similar in all mammalian species and mainly restricted to gray matter areas of the CNS, spinal cord, and retina. A severe nonpurulent poliomeningoencephalomyelitis with perivascular and parenchymal immune cell infiltrates accompanied by activation of astrocytes and microglia is characteristic. Diagnosis can be completed if pathognomonic intranuclear “Joest-Degen” inclusion bodies are present in neurons (Fig. 39.5). A loss of pyramidal cells of the hippocampus is noted occasionally but neuronal necrosis and neuronophagia are not regular features. The main affected brain areas are the olfactory bulb, basal cortex, caudate nucleus, thalamus, hippocampus, and periventricular areas of the medulla oblongata.

Despite the detection of viral antigen and infectious BDV in the retina in most affected horses, the retina is microscopically mostly unaffected, indicating central blindness.^{15,117} However, degeneration of retinal neurons resulting in blindness has been reported.⁶⁰ In contrast, BDV-infected rats and rabbits typically develop blindness caused by a nonpurulent chorioretinitis with degeneration of rods and cones.^{168,203,204}

Naturally infected horses display a similar composition of infiltrating immune cells (macrophages, CD4⁺ and CD8⁺ T cells, and plasma cells in chronic stages) and increased expression of MHC class I- and class II-antigens as described for experimentally infected rats.^{16,29,57,117} Thus, it can be assumed that the underlying neuropathogenesis is also immunopathologic in naturally infected hosts.

NATURAL INFECTION WITH ABV

Clinical Signs

Reports of natural cases and experimental studies provide evidence that ABV infections are the cause of PDD; ABV has been detected in 60% to 100% of PDD-affected birds investigated.^{79,92,112,131,132,152,213,218,246,259,309,340} Interestingly, ABV infections, as shown either by detection of viral RNA and/or

viral antigen, were also found in psittacines without clinical signs of PDD.^{50,111,119,132,172,218,327,352} Clinically healthy animals that only show ABV-specific antibodies are also described.

PDD was initially reported in macaws in the late 1970s and several synonyms—for example, macaw wasting disease, neuropathic gastric dilatation of psittacines, and myenteric ganglioneuritis—have been used.^{14,62,95,185} Up to now, PDD has been found in approximately 60 psittacine species that belong to 20 different genera, but also in some nonpsittacine species.^{48,55,95,132,222,343} Large parrots, including endangered species, seem to be affected most frequently and severely. Typical clinical signs of PPD are GI dysfunction and associated wasting with or without neurologic signs.^{14,95,132,185,309} Affected animals develop decreasing GI motility until stasis resulting in anorexia, lethargy, undigested seeds in the feces, regurgitation, diarrhea, weight loss leading to cachexia, and vomiting. Finally, affected birds die. Interestingly, there are also cases displaying only neurologic signs such as depression, ataxia, tremor, seizures, and motor or proprioceptive deficits. Blindness has been described in a few cases,³¹¹ and the mortality rate approaches 100%.⁹⁵

Pathogenesis

The incubation period of natural ABV infection is unknown and varied in experimental infections from approximately 20 to 60 days, up to 200 days.^{79,92,218,224} In these experiments, ABV-specific serum antibodies were detected between 7 and approximately 60 DPI and ABV RNA was detected in swabs between 20 and 72 DPI, depending on the route of inoculation (intracerebral, intramuscular, intravenous) and the bird species used, with the earliest detection of virus after intracerebral infection in cockatiels.^{79,92,218,224} Surveillance studies in aviaries with PDD cases revealed that birds displaying high viral RNA loads and high ABV-specific antibody titers are more likely to develop clinical PDD.¹¹¹ It should be noted that, similar to BDV infection, ABV-specific antibodies do not have any protective effect.^{111,218,224} A wide variation in the

clinical status of infected animals has been noted, including healthy animals that show typical histologic lesions at necropsy, clinically inconspicuous birds with widespread ABV distribution or restriction of viral RNA to the nervous tissue and any variation thereof.^{50,172,224,246,327,352} Asymptomatic carriers may contribute to virus dissemination. However, animals that did not become infected despite close contact to ABV-infected birds also exist.^{111,246}

Typical gross findings consist of emaciation with atrophy of pectoral muscles, dilatation or rupture of the proventriculus, and atrophy of the proventricular muscle (Fig. 39.6).^{95,185} Clinically manifest PDD is associated with characteristic mononuclear (lymphocytes, macrophages, plasma cells) infiltrates in ganglia and nerves of the enteric autonomous nervous system of crop, proventriculus, gizzard, and duodenum and, in most cases, non-purulent encephalitis, myelitis and/or ganglioradiculoneuritis of spinal nerves (Fig. 39.7).^{14,95,132,150,153,213,224,246,352} Gliosis and inflammation in peripheral nerves, myocardium, cardiac conductive tissue, and adrenal glands or eyes may also occur.

ABV shows a strong affinity for nervous tissue comparable to BDV, but broad peripheral tissue distribution is also seen. ABV RNA or antigen is most frequently found in the brain, spinal cord, and GI tract (crop, proventriculus, gizzard, small intestine) but often also in many other organs, for example, adrenal gland, eye, heart, liver, kidney, spleen, pancreas, lungs, gonads, thyroid, and skin (Fig. 39.8).^{119,153,218,224,246,259,340,341,352}

Many factors may contribute to the variability of the clinical picture and *in vivo* dissemination of ABV. Viral properties and host-specific features such as species, genetic background, age, immune competence, and the extent of contact with ABV-infected animals may influence the outcome of infection. It is unknown whether clinically apparent disease is due to similar immunopathologic processes as those in BD. Although similar inflammatory infiltrates and possibly virus persistence occurs, striking differences between ABV and BDV infection exist regarding the variability of clinical outcome, tissue tropism, and virus distribution.

Piepenbring and M. Lierz, Clinic for Birds, Reptiles, Amphibians and Fish, Faculty of Veterinary Medicine, Justus Liebig University Gießen, Germany.)

DIAGNOSIS

Differential Diagnoses

Neurologic signs of BD of mammals can be complex and variable so that a variety of CNS infections can result in a comparable clinical picture. Due to this lack of specificity, further laboratory tests are needed for a confirmed diagnosis. The differential diagnosis includes other neurotropic virus infections such as equine herpesviruses,³⁴⁸ rabies,⁹³ tick-borne encephalitis,¹⁹⁸ as well as bacterial diseases such as botulism³⁴⁵ and bacterial meningitis,⁷² and parasitic infections such as verminous myeloencephalitis⁶⁴ and equine protozoal myeloencephalitis (EPM).¹⁸³ In certain geographic regions, arthropod-borne flaviviruses (e.g., West Nile virus) and alphaviruses (e.g. western, eastern, Venezuelan equine encephalitis viruses) must also be considered.

Reliable *ante mortem* diagnosis of PDD and ABV infection has been problematic since clinical signs resembling PDD can also occur in other diseases such as bacterial, parasitic, or mycotic infection of the GI tract, ingestion of foreign bodies, intoxications or neoplasia, and the detection of ABV might be only intermittently possible.^{95,112,132,218} Thus, ABV infection and a diagnosis of PDD have to be confirmed by laboratory investigation.

systems, Western blot (WB) analysis, enzyme-linked immunosorbent assay (ELISA) and an indirect immunofluorescence assay (IFA) have been established (Fig. 39.9).^{23,91,120,122,124} IFA with BDV-infected and control cells is considered to be the most reliable method for the detection of BDV-specific

antibodies with high sensitivity and specificity.¹²² Titers of BDV-specific antibodies vary widely from 1:2 to 1:1280 in serum and CSF, and do not correlate with the clinical course of the infection.^{91,120} In very early stages of acute BD, or after treatment with corticosteroids, BDV-specific antibodies may

not be detectable. Clinically healthy horses can have BDV-specific antibodies in the serum but not in the CSF.^{91,120} In acute BD, the quantity of CSF protein content can be elevated and a mononuclear pleocytosis is regularly present.⁹¹ Evidence of infection including BDV RNA or BDV antigen in PBMC, or circulating immune complexes, has been presented by some investigators,^{23,58,200} but has been questioned by others.^{91,122} BD is reliably diagnosed *ante mortem* by neurologic signs combined with CSF pleocytosis and BDV-specific antibodies in serum and/or CSF.

As with BD in horses and sheep, signs and symptoms of PDD are not pathognomonic of ABV infection. Dilatation of the proventriculus and possibly other parts of the upper GI tract can be visualized by radiography/imaging techniques.⁵⁶ A definite diagnosis of PDD has to be substantiated by histopathologic examination of upper GI tract biopsies, which is hampered by the inconsistent distribution of lesions. Only the presence of mononuclear infiltrates of ganglia are confirmatory. In one study, crop biopsies revealed false negative

results in approximately 24% of cases.⁹⁴ ABV-specific serum antibodies can be demonstrated by WB assay,^{50,172,327} ELISA,⁵⁰ and IFA (Fig. 39.10).^{92,119} ABV infection has also been diagnosed by detection of ABV RNA in feces, swabs of crop and cloaca, blood, and feather calami using RT-PCR.^{49,92,153,172,259} The diversity of different ABV genotypes may require several RT-PCR assays. ABV genotypes 4 and 2 have been detected most frequently.^{79,92,153,194,224} Due to the possible intermittent presence of RNA in swabs and presence of ABV RNA and/or ABV-specific antibodies in clinically healthy virus carriers, repeated testing and the combined demonstration of ABV-specific serum antibodies and ABV RNA in crop and cloacal swabs currently represent the most reliable diagnostic approach.^{50,111,119,153,172,327}

Postmortem Diagnosis

For the postmortem diagnosis of natural BD, typical histopathologic lesions (Fig. 39.5), infectious virus and/or viral proteins and RNA in the CNS are usually demonstrated. Viral proteins are demonstrated by monoclonal or polyclonal antibodies recognizing the BDV N, P, M, X, or G proteins in immunohistochemical (IHC) approaches (Fig. 39.4) or WB analysis.^{15,91} Histopathology, IHC, WB, and nested RT-PCR gave identical diagnostic results in a comparative study of over 150 horses with or without BD.¹¹⁷ Furthermore, isolation of infectious BDV and demonstration of BDV RNA by *in situ* hybridization (ISH) (Fig. 39.4) can be used with adequately preserved tissue specimens.

Postmortem investigations in PDD show typical histopathologic lesions predominantly in the GI tract and CNS (Fig. 39.7). ABV RNA can be demonstrated not only in the nervous system and GI tract, but often in many other tissues.^{92,112,131,152,153,172,246,259,327,352} ABV RNA may be visualized by ISH³⁴¹ and ABV protein by IHC, applying either cross-reactive anti-BDV antibodies against the N, P, or X-protein, or ABV-specific antibodies against the N protein (Fig. 39.8).^{119,213,224,246,259,340,352} However, the monoclonal anti-BDV N antibody Bo18 that is widely used for diagnosis of mammalian BDV infections consistently gives negative results with ABV. Virus isolation has been successful in the quail cell lines CEC-32 and QM7^{119,259} or duck embryo fibroblasts.⁹²

THERAPY AND CONTROL

Vaccination

Although there is only limited experience with vaccines in BD, better success has been reported with live attenuated than with killed virus vaccines.^{46,210} A lapinized live vaccine³⁶² was used for many years in the eastern federal states of Germany. Because efficacy was questionable, and there were concerns regarding the possible post-vaccination shedding of infectious virus as well as potential establishment of a persistent virus reservoir, the vaccine was abandoned in 1992.^{196,287} High virus titer may be important for the successful implementation of live vaccines.^{196,287} Cell-culture attenuated BDV protected rats against intracerebral challenge with a virulent inoculum only when administered at high titer (10^5 – 10^6 vs. 10^2 – 10^4).²¹⁰ Similarly, a high dose of another extensively passaged virus resulted in strong humoral and cellular immunity. A lower dose inoculum did not provide this protection.⁷⁶ Neither of these studies investigated virus shedding by the vaccinated animals or the biology of progeny virus.

There have been several efforts to develop recombinant BDV vaccines. A vaccinia virus recombinant expressing BDV N primed rats for enhanced viral clearance after challenge, but also for aggravated disease due to increased immunopathology.¹⁷¹ More recently, expression of BDV N by a parapoxvirus vector system was reported to protect rats from challenge.¹¹⁵ No data are available on vaccines based on BDV G; however, the observation that a monoclonal anti-G antibody was protective in rats suggests that such an approach could be successful.⁷⁷

Therapeutics

Amantadine sulfate (AS), a drug with antiviral activity against influenza A,¹¹⁰ inhibits replication of certain human and horse

BDV isolates in cell culture and improves the clinical course in some subjects with affective disorders.^{19,20,59} However, the efficacy of AS for treatment of persistently BDV-infected cell cultures and animals is controversial.^{41,101,316} In a small clinical study of horses with acute BD, AS (2 mg/kg orally) had no effect in 8 out of 9 animals.⁹⁰

Ribavirin inhibits transcription and replication of both He/80 and strain V BDV in a variety of cell lines.^{143,195} In addition to its antiviral effects through depletion of cellular GTP pools, interference with mRNA capping, and direct interaction with viral polymerases, ribavirin can promote a Th₁-type immune response.^{137,319} This led to concerns that enhancement of cellular immunity might aggravate immunopathology of BD.^{104,171,297} In one study, the efficacy of ribavirin administered directly to the brain by intraventricular injection was assessed in the rat model. Although ribavirin had no effect on viral load, treated animals had less inflammation and milder disease presumably due to antimitotic effects on microglia.³⁰⁶ In another animal model, the Mongolian gerbil, in which BDV can cause direct neuronal damage independent of immunopathology,³³⁶ ribavirin at a higher dosage than tolerated in the rat model reduced virus load in the brain.¹⁷⁰

1-β-D-arabinofuranosylcytosine (Ara-C) inhibits BDV replication in cultured cells and inhibits viral replication, improving clinical outcome in infected rats.^{6,47} Ara-C is a DNA polymerase inhibitor and has no effect on polymerases of influenza or measles viruses, but has antiviral activity against rabies virus.²⁸ In BDV, Ara-C appears to act as a competitive inhibitor of cytidine.³²⁹ A related cytosine nucleoside, 2'-fluoro-2'-deoxycytidine, shows similar antiviral activity *in vitro* and may be preferable due to its reduced cytotoxicity.⁷

At present, there is no curative therapy for PDD or ABV infection; symptomatic treatment is the only option. Methods for ABV infection control and prevention include appropriate management practices in aviaries such as isolation of ABV-infected birds, sanitation, and disinfection.¹³² Control of traffic and trading may help to impede spread in the pet bird population.

PERSPECTIVES AND PUBLIC HEALTH CONSIDERATIONS

In the last 20 years, substantial progress in BD research has been achieved regarding the molecular characterization of the causative agent, underlying immunopathogenesis, mechanism of viral persistence, and natural distribution of BD. However, we still know little about its ecology and epidemiology, especially the identity of reservoirs and mechanisms for natural transmission. Also, a novel bornavirus, ABV, was discovered in a variety of avian species. The worldwide epidemiology of BD in various warm-blooded animals remains controversial. Virulence of the virus and genetic predisposition of the host or other exogenous and endogenous factors might play a role in the outcome of infection. Although the genomic fossil record indicates infection of primates, including human ancestors up to 40 million years ago, there is no convincing evidence of human infection. The intriguing properties of BDV are providing insights into cellular trafficking, neural circuitry, neural

development, and immunopathology of CNS infections. Further investigations will improve our understanding of the complexity of the disease mechanisms, BDV-associated disorders, and the epidemiology of BD.

Perspectives

Influenza viruses were probably responsible for the disease described by Hippocrates in 412 BC,²⁷⁵ and thus they have been with us for a long, long time. Influenza remains a major cause of morbidity and mortality worldwide, and large segments of the human population are affected every year. In addition, many animal species can be infected by influenza viruses, and some of these viruses may give rise to pandemic strains in humans, as in the case of the 2009 H1N1 pandemic. Most threatening is the possibility of another pandemic similar to that experienced in 1918, which is estimated to have caused on the order of 50 million deaths worldwide.³¹⁹

CLASSIFICATION

The family of *Orthomyxoviridae* is defined by viruses that have a negative-sense, single-stranded, and segmented RNA genome. The definition of negative-sense RNA viruses came

from work by David Baltimore, who showed that the packaged genome of this class of viruses is complementary to the messenger RNA (mRNA), which is defined as positive.²¹ There are six different genera in the family of *Orthomyxoviridae*: the *Influenzaviruses A, B, and C*; *Thogotovirus*; *Isavirus*; and a new genus, *Quaranfilvirus*⁵²⁶ (Fig. 40.1). Members belonging to any of the three different genera of influenza viruses can undergo genetic reassortment (see below), and thus readily exchange genetic information. However, reassortment between members of different genera (types) has never been reported. This absence of genetic exchange between viruses of different genera (types) is one manifestation of speciation as a result of evolutionary divergence.

Different influenza virus strains are named according to their genus (type), the species from which the virus was isolated (omitted if human), location of the isolate, the number of the isolate, the year of isolation, and, in the case of the influenza A viruses, the hemagglutinin (H) and neuraminidase (N) subtypes. For example, the 220th isolate of an H5N1 subtype virus isolated from chickens in Hong Kong in 1997 is designated influenza A/chicken/Hong Kong/220/97(H5N1) virus. There are now 17 different hemagglutinin (H1 to H17) subtypes and 9 different neuraminidase (N1 to N9) subtypes for influenza A viruses as well as a new N10 neuraminidase,^{186,668,721} while the influenza B virus hemagglutinins and neuraminidases are each classified into two lineages (Fig. 40.2).

VIRION STRUCTURE

Influenza A viruses have a complex structure and possess a lipid membrane derived from the host cell (Fig. 40.3A). This envelope harbors the hemagglutinin (HA), the neuraminidase (NA), and the M2 proteins that project from the surface of the virus. The matrix protein (M1) lies just beneath the envelope, and the core of the virus particle is made up of the RNP (ribonucleoprotein) complex, consisting of the viral RNA segments, the polymerase proteins (PB1 [polymerase basic 1], PB2 [polymerase basic 2], and PA [polymerase acid]), and the nucleoprotein (NP).⁶⁰¹ The NEP/NS2 (nuclear export protein/nonstructural protein 2) protein is also present in purified viral preparations.⁵⁵⁶ The overall composition of virus particles is about 1% RNA, 5% to 8% carbohydrate, 20% lipid, and approximately 70% protein.^{2,116,188} However, these results will have to be revisited using more quantitative approaches. Specifically, it will be important to get more quantitative data on the presence of individual viral components as well as cellular components that are packaged into the virus.⁶⁰² Excellent analyses have already been performed using electron

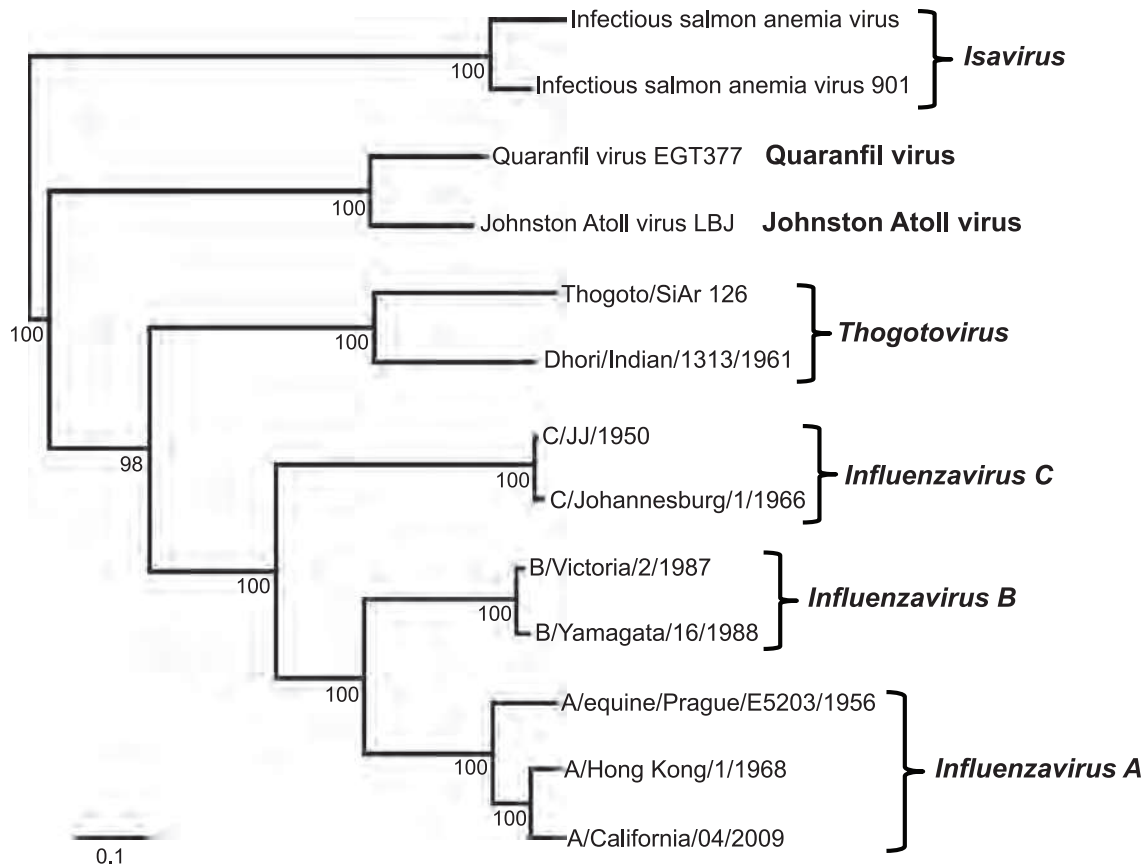

FIGURE 40.1. Phylogenetic relationships within the family *Orthomyxoviridae*. Nucleotide sequences of the polymerase basic 1 proteins (PB1) were aligned using transAlign and CLUSTAL W, and their phylogenetic relationships were determined by the neighbor-joining method (HKY model) using PAUP* (version 4.0b). The tree was midpoint rooted and bootstrap values (1,000 replicates) are indicated on the branches. The GenBank accession numbers for the sequences used for comparison were (top to bottom) AF404346, GU830904, FJ861695, FJ861697, AF004985, M65866, M28060, AF170575, CY018763, CY018771, GU053121, CY044267, and FJ966080. (Adapted from Perez D, Rimstad E, Smith G, et al. *Orthomyxoviridae*. In: King AMQ, Adams MJ, Carstens EB, et al, eds. *Virus Taxonomy*. Oxford, UK: Elsevier, 2011:749–762.)

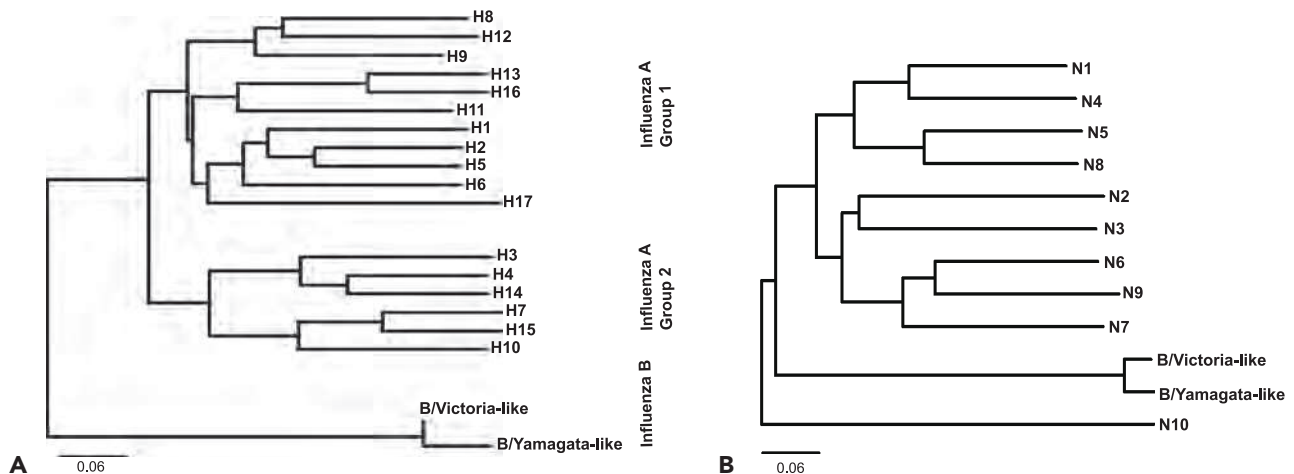

FIGURE 40.2. Phylogeny of influenza A and B virus hemagglutinins (HAs) and neuraminidases (NAs). Rooted phylogenetic trees are based on amino acid sequences of HA (A) and NA (B) segments from influenza A and B viruses. Representative viruses were selected from GenBank and then aligned using ClustalW. Phylogenetic trees were constructed using FigTree software. The scale bars represent approximately 6% amino acid changes between close relatives. (Courtesy of Natalie Pica.)

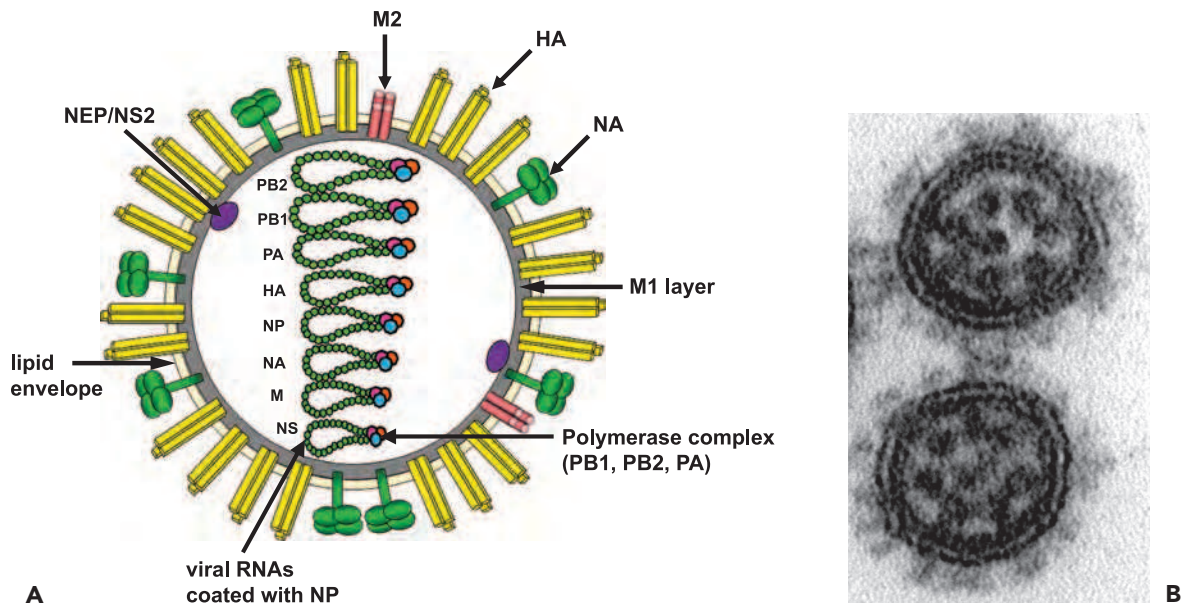

FIGURE 40.3. Schematic diagram and electron micrograph of influenza virus particles. **A:** The hemagglutinin (HA), neuraminidase (NA), and M2 proteins are inserted into the host-derived lipid envelope. HA is found as a trimer and NA and M2 both as tetramers. The matrix (M1) protein underlies the lipid envelope. A nuclear export protein (NEP/NS2) is also associated with the virus. The viral RNA segments are coated with nucleoprotein and are bound by the polymerase complex. **B:** Electron micrograph thin section image of influenza virus particles (diameter ~100 nm) with the HA and NA spikes visible on the surface and the eight ribonucleoprotein (RNP) segments visible in the interior of each particle. (Courtesy of Yi-ying Chou.)

microscopy (EM) of negatively stained or frozen-hydrated (cryoelectron microscopy) particles and tomographic reconstructions.^{80,192,256,464,489} The morphology of influenza A virus particles is characterized by distinctive spikes that are readily observable in electron micrographs of negatively stained virus particles (Fig. 40.3B). These spikes, made up of HA and NA, have lengths of ~10 to 14 nm, with an approximate ratio of four HA to one NA. Influenza viruses are pleomorphic. The spherical particles have a diameter of about 100 nm, but filamentous particles with elongated viral structures (more than 300 nm) have frequently been observed, particularly in fresh clinical isolates¹⁰² and in preparations of viruses with specific M1 or M2 proteins (e-Fig. 40.1).^{55,77,159,571}

Less is known about the internal structures of influenza viruses. However, the underlying M1 layer can be visualized and reveals a helical superstructure.^{80,575,577} The RNP complexes were first separated by Duesberg¹⁴⁷ on sucrose gradients and were visualized by electron microscopy using positive staining with uranyl acetate.¹¹⁵ These RNP structures appear to consist of a strand that is folded back on itself to form a double-helical arrangement.¹¹⁵ Most recently, attempts have been made to visualize RNPs or individual RNA segments by electron microscopy of thin sectioned virus particles⁴⁸⁹ (for review see (488)).

Influenza B viruses are mostly indistinguishable from the A viruses by electron microscopy. They have four proteins inserted in their lipid envelopes: the HA, NA, NB, and BM2.^{38,62,491,757} The M1 and the RNP complexes make up the interior of the particle. It has also been shown that the influenza B virus NEP/NS2 is associated with purified virus preparations.³⁰⁴

Influenza C viruses have been found to possess hexagonal reticular (net-like) structures on the surface¹⁰ and to form

unusually long (500 μ m) cord-like structures on the surface of infected cells.^{461,484} Influenza C viruses also contain a core of three polymerase proteins and the NP, which are associated with seven RNA segments. The influenza C virus M1 appears to have a similar role to those of influenza A and B viruses. The major glycoprotein, HEF (hemagglutinin-esterase-fusion), combines the functions of the HA and NA (and thus influenza C viruses contain one less RNA segment than do the A and B viruses). The HEF is inserted into the lipid membrane, as is the glycosylated CM2, which is structurally analogous to the M2 of influenza A viruses and the NB of influenza B viruses.^{466,467,524}

GENOME STRUCTURE AND ORGANIZATION

Influenza Viruses

All A- and B-type influenza viruses possess eight RNA segments, whereas influenza C viruses only have seven RNAs (Fig. 40.4 and e-Figs. 40.2 to 40.4). This was first shown by using polyacrylamide gel electrophoresis of isolated RNAs from two parent influenza A virus strains and their reassortants. Identifying the derivation of an RNA segment (by gel electrophoresis) in a reassortant and simultaneous protein analysis (by serologic or gel analysis) allowed the assignment of individual RNAs to specific viral proteins^{508,513,514} (for review, see (509)) (Fig. 40.5 and e-Fig. 40.4). Interestingly, influenza A viruses increase the coding capacity of their genomes via both splicing and use of alternative open reading frames. The M and NS genes each give rise to a spliced mRNA encoding the M2 and the NEP/NS2 proteins, respectively.^{354,355} The PB1-F2 and PB1 N40 proteins are expressed from alternative open reading frames

FIGURE 40.4. Genome structure of influenza A/Puerto Rico/8/34 virus. RNA segments (nucleotides in black) shown in positive sense and their encoded proteins (amino acids in red). The lines at the 5' and 3' termini represent the noncoding regions. The polymerase basic 1 protein (PB1) segment contains a second open reading frame (ORF) in the +1 frame resulting in the PB1-F2 protein and a third ORF in the 0 frame resulting in the PB1 N40 protein. The M2 and nuclear export protein (NEP/NS2) proteins are encoded by spliced messenger RNAs (mRNAs) (the introns are indicated by the V-shaped lines). (Courtesy of Heinrich Hoffmann.)

within the *PB1* gene^{93,726} (Fig. 40.4), although not all influenza A virus strains encode these proteins, making them true accessory proteins. Each viral segment contains noncoding regions at both the 5' and 3' ends. The extreme ends are conserved among all segments of influenza A viruses and this is followed by a segment-specific noncoding region.

The influenza B virus genome is similar to that of influenza A virus. Again, eight RNA segments code for one or more viral proteins (e-Figs. 40.2 and 40.4) with the three largest RNAs coding for the polymerase proteins, the fourth RNA for the HA, and the fifth and sixth RNAs for the NP and NA, respectively.⁵⁵⁰ The NA gene codes for the NB protein as well as for the NA. The NB protein is encoded by a -1 open reading frame seven nucleotides upstream (...AUGAACA AUG...) of the NA coding frame.⁶⁰³ The seventh RNA codes for the M1 protein (248 amino acids in length). Its termination codon (...UAAUG) overlaps with the initiation codon (UAAUG...) for the BM2 (109 amino acids in length), which allows for a "stop-start" translation mechanism.²⁸⁸ The eighth RNA codes for the NS1 as well as for the NEP/NS2 protein, the latter via a

spliced mRNA. Cognate PB1-F2 and PB1 N40 proteins have not yet been identified in influenza B viruses. The noncoding regions of the influenza B virus genome are longer than those in influenza A virus.

The genome of influenza C viruses has only seven RNA segments, with the three largest RNAs each coding for one of the polymerase proteins (e-Figs. 40.3 and 40.4). The PB1 and PB2 proteins are homologous to the corresponding influenza A and B virus proteins. The third influenza C virus polymerase protein is named P3 because it does not display acid charge features at neutral pH, as do the corresponding PA proteins of influenza A and B viruses.⁷⁴⁰ The fourth RNA codes for the HEF protein,²⁷¹ combining the hemagglutinin, receptor-destroying, and fusion activities. The NP is encoded by the fifth RNA. The sixth RNA codes for the M protein, which is expressed from a spliced mRNA, and from the unspliced mRNA a long precursor is translated (p42), which is then processed by signal peptide cleavage into CM2. This 115-amino acid (aa)-long protein consists of an amino-terminal extracellular domain (with a carbohydrate chain), a hydrophobic transmembrane domain, and an

FIGURE 40.5. RNA segments of influenza A/Puerto Rico/8/34 (H1N1) and A/Hong Kong/8/68 (H3N2) viruses. The viral RNAs are separated on a polyacrylamide gel and the proteins encoded by the RNAs are indicated. (Adapted from Palese P. The genes of influenza virus. *Cell* 1977;10[1]:1–10.)

intracellular cytoplasmic tail.^{523,524,741} Finally, RNA 7 codes for the NS1 protein (246 amino acids),⁴⁶⁷ and via a spliced mRNA, for the NEP/NS2 protein (182 amino acids).^{5,284}

Evolutionarily, influenza A, B, and C viruses have a common precursor, and it is also likely that influenza A and B viruses diverged from each other more recently than influenza C viruses. Based on comparative sequencing studies using the hemagglutinin molecules, it has been postulated that the influenza A viruses diverged about 2,000 years ago, and the influenza B and C viruses about 4,000 and 8,000 years ago, respectively.⁶⁵³ Clearly, these numbers are based on a series of unprovable assumptions, including a steady rate of evolution over time, and therefore must be taken *cum grano salis*.

Thogoto Virus

The genomes of Thogoto viruses possess only six single-stranded RNA segments of negative polarity, with a total coding capacity for seven proteins. As with the influenza viruses, three proteins make up the RNA-dependent RNA polymerase complex. The NP, the glycoprotein (G), the matrix protein (M), and one non-essential accessory protein (ML) are coded for by the remaining three RNAs. The M and ML proteins are both encoded by the shortest RNA, with the M protein being derived from a spliced mRNA.^{242,339} The 304-aa-long ML protein has been shown to possess interferon antagonist activity^{69,242,316} and is virion associated.²⁴¹ It appears that Thogoto viruses do not possess a nonstructural protein.

Infectious Salmon Anemia Virus

The genome of infectious salmon anemia virus consists of eight negative-sense, single-stranded RNA segments.^{122,447} Segment 1 most likely encodes a protein analog of the influenza virus PB2.⁶²⁶ The second segment appears to code for a PB1 analog because it carries the PB1-specific polymerase motifs.⁶²⁶ Segments 3 and 4 code for the NP and PA proteins, respectively.^{15,169} Segment 5 encodes the 50-kD F (fusion) protein, and segment 6 encodes the HA (hemagglutinin-acetylesterase) protein.^{16,169,526} The 42-kD HA has been demonstrated to bind to 4-O-acetylated sialic acid (i.e., to use it as a receptor) and also to hydrolyze the acetyl group.²⁶⁷ This activity is similar to the binding and receptor-destroying enzyme (RDE) activities previously observed for the HEF protein of influenza C viruses and the HE glycoprotein of coronaviruses.^{267,271,685–687} Segment 7 encodes two proteins via an alternative splicing mechanism.⁴⁰ The larger protein is expressed from the unspliced transcript and has interferon antagonist activity.^{211,430} Segment 8 encodes two proteins of 27.6 kD and 22 kD, the larger of which has interferon antagonist activity.^{122,211} The smaller protein is a structural protein, presumed to be the equivalent of the influenza virus matrix protein.¹⁶⁹

Quarantfil Virus

The genome of *Quarantfil virus*, which is the type species of the new *Quarantfilvirus* genus, consists of six negative-sense, single-stranded RNA segments.⁵²⁶ The ends of each segment are conserved and partially complementary. Segments 1, 2, and 3 encode the PB2, PA, and PB1 polymerase subunits, respectively, while segment 5 codes for a protein that is distantly related to the Thogoto virus glycoprotein, and thus is likely the attachment protein.⁵⁴⁴ The predicted protein products of segments 4 and 6 do not show any homology with known proteins.

STAGES OF VIRAL REPLICATION

An overview of the influenza virus life cycle is illustrated in Figure 40.6 and in the following pages we will discuss each stage of this life cycle in order.

Mechanism of Attachment

Influenza viruses bind to neuraminic acids (sialic acids) on the surface of cells to initiate infection and replication. The interaction of influenza viruses with a ubiquitous molecule such as sialic acid is constrained by the fact that the HAs of viruses that replicate in different species show specificity toward sialic acids with different linkages. Human viruses preferentially bind to N-acetylneuraminic acid attached to the penultimate galactose sugar by an α 2,6 linkage (SA α 2,6Gal), whereas avian viruses mostly bind to sialic acid with an α 2,3 linkage¹²⁰ (e-Fig. 40.5). In agreement with this finding is the fact that human tracheal epithelial cells contain mostly SA α 2,6Gal, while the gut epithelium from ducks possesses mostly SA α 2,3Gal sugar moieties.^{123,307} It should be noted, however, that this viral specificity is not absolute and that avian and human cells can contain both neuraminic acid linkages (2,3 as well as 2,6). Studies on ciliated cells in the human airway epithelium have shown that sialylated proteins with α 2,3 linkages are present and that these cells can be infected with avian influenza viruses.⁴²⁵ Furthermore, glycan structure is far more complex than just the terminal sialic acid

FIGURE 40.6. Illustration of the influenza virus replication cycle. Upon binding at the cell surface, the virus is internalized by receptor-mediated endocytosis. The low pH in the endosome triggers fusion of the viral and endosomal membranes, releasing the viral ribonucleoproteins (vRNPs) into the cytoplasm. vRNPs are imported into the nucleus where they serve as the template for transcription. New proteins are synthesized from viral mRNA. The viral genome (vRNA) is replicated through a positive-sense intermediate (complementary RNA [cRNA]). Newly synthesized viral RNPs are exported from the nucleus to the assembly site at the apical plasma membrane, where virus particles bud and are released.

linkage, and evidence suggests that factors such as the type of backbone, chain length, and branching pattern as well as sulfation and fucosylation may also influence the interactions with HA.^{99,639} Glycan microarrays that contain a wide spectrum of glycan structures are now being used as tools to better understand the specificity of receptor binding.⁶³⁸ Also, when viruses are passaged in a particular host, they can adapt to that host by mutating the receptor-binding site in the viral HA.^{202,448} In a study of the A/New York/1/1918 virus HA, it was shown that the binding specificity can be changed by a single amino acid mutation (D190E) to a preference for α 2,3-linked sialic acids. It is thus hypothesized that the HA gene of the 1918 influenza virus has its origin in avian species and that a single amino acid change (E190D) allowed the hemagglutinin to recognize the α 2,6-linked sialic acids prevalent in human cells.^{222,637}

Mechanism of Entry

While some viruses (e.g., paramyxoviruses and herpes viruses) can enter cells directly through the plasma membrane by a pH-independent fusion process, influenza viruses require a low pH to initiate fusion and are therefore internalized by endocytic compartments. There are four internalization mechanisms: (a) via clathrin-coated pits; (b) via caveolae; (c) through nonclathrin, noncaveolae pathways; and (d) through macropinocytosis (for review, see (119,353,443,613)). Clathrin-mediated endocytosis has traditionally been the model for influenza virus entry.⁴²⁴ However, a non-clathrin, non-caveolae-mediated internalization mechanism has also been described for influenza viruses.⁶¹² The latter pathway is dependent on low pH and trafficking to late endosomes, as it requires protein kinase C, Rab5, and Rab7 functions.⁶¹¹ More recently, through the use of specific inhibitors and RNA interference (RNAi), it has been shown that in addition

to entering via a dynamin-dependent, clathrin-driven pathway, influenza viruses can also enter via a dynamin-independent pathway that is characteristic of macropinocytosis.¹³³ Potential differences in the entry pathways defined in polarized versus nonpolarized cells should also be appreciated, as, for example, the actin cytoskeleton appears to be critical for uptake of influenza viruses into polarized cells but not nonpolarized cells.⁶⁵¹ The requirement of specific host proteins during influenza virus entry will help to further define the cellular pathways utilized by the virus. Genome-wide RNAi screens have identified multiple factors that are required for efficient entry mediated by the influenza virus glycoproteins³⁴¹; however, the ability of the virus to enter via different routes means that this approach is unlikely to capture factors that are specific to one endocytic route. A more focused approach, such as that which shows the requirement of epsin 1 for clathrin-mediated uptake of influenza virus, is needed.⁹⁰ The epidermal growth factor receptor (EGFR) has also been demonstrated to play a role during influenza virus entry,¹⁵⁴ and it is thought that virus attachment to the cell stimulates EGFR, which leads to activation of signaling cascades such as phosphatidylinositol 3 kinase (PI3K) signaling, which is known to promote influenza virus entry.¹⁵² There are also questions over whether sialic acid is the only attachment molecule. Lec-1 cells, which are deficient in N-linked glycosylation (but still contain sialylated proteins), are unable to internalize influenza viruses.¹⁰³ Similarly, cells deficient in sialic acid can be made to support influenza virus entry if they express one of the C-type lectins, DC-SIGN or L-SIGN.³⁹⁸

Mechanism of Fusion and Uncoating

Influenza viruses and other enveloped viruses (including rabdo-, flavi-, bunya-, and filoviruses) require low pH to fuse

with endosomal membranes. After binding to the target cell surface and endocytosis, the low pH of the endosome activates fusion of the viral membrane with that of the endosome. This fusion activity is induced by a structural change in the HA of influenza viruses, but in order for this to occur, the HA0 precursor must first be cleaved into two subunits, HA1 and HA2. Once in the acid environment of the endosome, the cleaved HA molecule undergoes a conformational change and this exposes the fusion peptide at the N-terminus of the HA2 subunit, enabling it to interact with the membrane of the endosome (for review, see (128,258,632) and for details see the following section on Hemagglutinin). The transmembrane domain of the HA2 (inserted into the viral membrane) and the fusion peptide (inserted into the endosomal membrane) are in juxtaposition in the low pH-induced HA structure. The concerted structural change of several hemagglutinin molecules then opens up a pore, which releases the contents of the virion (i.e., viral RNPs) into the cytoplasm of the cell. The precise timing and the location of uncoating (maturity of the endosome) depends on the pH-mediated transition of the specific HA molecule involved.

The uncoating of influenza viruses in endosomes is blocked by changes in pH caused by weak bases (e.g., ammonium chloride or chloroquine) or ionophores (e.g., monensin) (for review, see (418)). Effective uncoating is also dependent on the presence of the M2 protein, which has ion channel activity.^{532,534} Early on it was recognized that amantadine and rimantadine inhibit replication immediately following virus infection.⁶¹⁷ Later it was found that the virus-associated M2 protein allows the influx of H⁺ ions from the endosome into the virus particle, which disrupts protein–protein interactions and results in the release of RNP free of the M1 protein.^{424,767} (for review, see (534)). Amantadine and rimantadine have been shown to block the ion channel activity of the M2 protein and thus uncoating.^{100,281,532,648,699} The HA-mediated fusion of the viral membrane with the endosomal membrane and the M2-mediated release of the RNP result in the appearance of free RNP complexes in the cytoplasm. This completes the uncoating process.⁴²¹ The time frame for the uncoating process was examined by inhibiting virus penetration with ammonium chloride. The majority of virus particles showed a half time for penetration of about 25 minutes (after adsorption). Barely 10 minutes later (half time of 34 minutes after adsorption) RNP complexes are found in the nucleus.⁴²¹ The process for uptake of RNP molecules through nuclear pores is an active one, involving the nucleocytoplasmic trafficking machinery of the host cell (for details, see Nuclear Import of RNPs).

Much less is known about the uptake and uncoating of influenza B and C viruses. Influenza B viruses are more like influenza A viruses as both recognize N-acetylneuraminic acid as receptors, while influenza C viruses bind to 9-O-acetylated neuraminic acid derivatives.²⁷² Like influenza A viruses, the B- and C-type viruses go through an endosome-mediated uncoating process, which requires proteolytic activation (cleavage) of the HA or HEF proteins and subsequent fusion of the viral and endosomal membranes. Although the viral glycoproteins of both viruses are dependent on a low pH-triggered fusion process, the influenza C virus HEF-mediated fusion/uncoating may occur at a higher pH in early endosomes.^{184,767} At this point, the role of CM2 in uncoating of influenza C viruses is less well established than that of the BM2 protein of influenza

B viruses, which is the homolog of the influenza A virus M2 protein.^{193,253,262,283,455,701}

The Hemagglutinin

STRUCTURAL FEATURES

Much is known about the HA molecule and excellent reviews are available.^{150,204,258,613,618,633,658} In fact, the influenza virus HA has become a model for studies of protein folding and trafficking, protein quality control, membrane fusion, protein–receptor interactions, and antigen–antibody complexes and, last but not least, for investigating how the immune system reacts to a foreign protein. The major functions of the HA are the receptor-binding and fusion activities, but there may also be a structural role for the HA in budding and particle formation. The HA is a trimeric rod-shaped molecule with the carboxy terminus inserted into the viral membrane and the hydrophilic end projecting as a spike away from the viral surface (i.e., a type I integral membrane protein). Early on it was shown that (a) posttranslational modifications of the precursor molecule (i.e., glycosylation and palmitoylation), (b) cleavage of the signal peptide in the endoplasmic reticulum (ER), and (c) cleavage of the HA0 precursor into HA1 and HA2 subunits are required for the full activity of the molecule.^{335,363,542}

The first x-ray crystallographic structure of an HA (the ectodomain released from the virus by bromelain treatment) was resolved in 1981 by Wilson et al.⁷²⁵ At that time the HA (from A/Aichi/68 [H3N2] virus) was the largest biological molecule for which a structure had been resolved, and it started an unprecedented drive to study the structure/function relationships of biologically important molecules, which continues unabated to this day. The structures of numerous HAs have now been resolved, including the subtype 1 HA molecules of the 1918 and 2009 pandemic influenza viruses^{203,640,735} and that of an H2 subtype HA⁷³⁶ (Fig. 40.7). Remarkably, even though the overall amino acid sequence identity can be less than 50%, the structure and functions of these HAs are highly conserved (e-Fig. 40.6). This represents a case of evolution and sequence variation proceeding to an extreme level while structure and function have remained conserved. Even more surprising is that the structure of the influenza B virus HA is similar to that of influenza A virus HA despite sharing only 25% sequence identity.^{703,704}

The crystallographic structure of the uncleaved influenza A virus HA is superimposable onto that of the cleaved HA1 and HA2, with the exception of the amino acids adjacent to the cleavage site. The major features of the structure are (a) a long fibrous stem, which is made up of a triple-stranded coiled coil of α -helices derived from the three HA2 parts of the molecule (helix A and helix B; Fig. 40.7 and e-Fig. 40.6), and (b) the globular head, which is also made up of three identical domains whose sequences are derived from the HA1 portions of the three monomers. The *first major function* of HA is binding to receptors and the receptor-binding site lies within the globular head of the molecule. This site has been defined through crystallization and structure analysis of HA–receptor complexes, as well as by mutational analysis. In the H3-subtype viruses, it appears that within the receptor-binding pocket of an avian HA, a glutamine in position 226 preferentially accommodates the 2,3-linked sialic acid, whereas a leucine in that position in human H3 HAs preferentially accommodates the 2,6-linked sialic acid²³⁹ (e-Fig. 40.7). (See the previous section on Attachment for more details).

FIGURE 40.7. Ribbon representation of the uncleaved hemagglutinin monomer from the 1918 influenza virus based on x-ray diffraction analysis. The five predicted antigenic sites (Ca2, Sb, Sa, Ca1, and Cb) surround the sialic acid receptor-binding site. Toward the membrane proximal end (bottom) is the fusion peptide and helices A and B are indicated. For details see (640). (Courtesy of James Stevens and Ian Wilson.)

The *second major function* of the HA is acid pH-triggered fusion, which is required for the uncoating process. Low pH treatment changes the structure of the HA dramatically. The molecule becomes susceptible to protease digestion, and the disulfide bond linking the HA1 and HA2 subunits becomes susceptible to mercaptoethanol.^{232,615} However, the important feature of the acid pH-mediated change is that the fusion peptide becomes aligned antiparallel to the membrane anchor of the HA2 (Fig. 40.8). The end result is that the fusion peptide brings the endosomal membrane into juxtaposition with the viral membrane, leading to fusion. The presence of more than one hemagglutinin then leads to the formation of a fusion pore through which the RNP can enter the cytoplasm (Fig. 40.9). Structures of the postfusion HA as well as an early fusion intermediate have helped to reveal the molecular details of the changes that occur during the transition from pre- to postfusion state.^{75,737} Structures of the fusion peptide in lipid environments have been resolved by nuclear magnetic resonance

(NMR) and show that the peptide forms a tight helical hairpin structure that angles back on itself^{252,351,399} (e-Fig. 40.8). This hook structure may help to pull the endosomal membrane close to the viral membrane, resulting in the initiation of the actual fusion process. These studies represent the first foray into the characterization of the transmembrane region, which so far has proved difficult to analyze.

The third major structural element of the HA, the cytoplasmic tail, is highly conserved among all subtypes. There are three cysteines that are palmitoylated (with one of them located in the transmembrane domain). The role of this cytoplasmic tail (and the palmitates attached to the cysteines) is not entirely clear due to subtype- and cell/host-specific differences.^{89,318,439,696,774}

ANTIGENIC DETERMINANTS

In addition to having an important role in receptor binding, fusion, and assembly, the influenza virus HA is also the *major determinant* recognized by the adaptive immune system of the host. Following infection and replication, a vigorous immune response is induced, which usually results in the formation of neutralizing antibodies. These antibodies then lead to the selection of “antibody escape” variants. The amino acids undergoing change are almost exclusively on the HA1 (and on the outside of the molecule). Many of these changes get fixed (accumulate over time), defining the antigenic drift of influenza viruses (e-Fig. 40.9). Fab antibody fragments have been shown to bind to different regions of the HA1 (e-Fig. 40.10) and, interestingly, not in all cases do three Fabs bind to one trimeric spike (3:1 ratio). Examples have been found where only one Fab molecule binds to one HA spike (1:1 ratio) or where just two Fab molecules bind to a trimeric spike (2:1 ratio) (e-Fig. 40.10).³³⁶ In the latter case, the two Fab fragments cross-link the two monomers so that the HA molecule cannot undergo an acid pH-induced conformational change.³³⁶ Attempts have also been made to measure antigenic evolution of influenza virus strains by pairwise comparison of hemagglutination inhibition assays.^{187,622}

Unexpectedly, broadly cross-reactive monoclonal antibodies have been identified, which do not bind to the tip of the HA molecules but also have neutralizing activity.^{121,157,327,495,650,663,730} These antibodies are directed against the conserved stem region of the HA spike and recognize the membrane-proximal part of HA1 in combination with HA2 or the HA2 alone (Fig. 40.10).⁷⁰⁷ In general, these antibodies recognize the HAs within either group 1 (for review see (706)) or group 2,^{158,707} but recently a human monoclonal antibody was described that binds to the stem of both group 1 and group 2 HAs.¹²¹ The most likely mechanism by which these cross-reactive antistem antibodies neutralize influenza viruses is by blocking conformational rearrangements associated with membrane fusion (antifusion vs. hemagglutination inhibition activity). A broadly neutralizing human monoclonal antibody that recognizes the highly conserved sialic acid-binding site of H1 HAs has also been described.³⁴³ It is hoped that the conserved epitopes identified by these cross-protective antibodies could be utilized as immunogens with the possibility of developing novel vaccine constructs that will result in effective and safe universal influenza virus vaccines.^{47,631,708}

The HEF of Influenza C Viruses

In contrast to the HA of influenza A and B viruses, the major glycoprotein of the C viruses has a receptor-destroying activity.

FIGURE 40.8. Ribbon representation of the structural changes that occur in hemagglutinin (HA) at low pH. Bromelain-treated HA monomer with regions of HA2 undergoing conformational changes at low pH as indicated by numbered domains (**left**). The domains, starting at the fusion peptide (domain 1), are numbered sequentially until the membrane anchor is reached (domain 6). The structure and the position of the region comprising residues 75 to 106 (domain 4) are the same before and after the conformational change (denoted by the dotted lines). The globular head domains retain their structures but detrimerize (falling to the right, away from the HA2 portion). For details see (92) and (616). (Courtesy of John Skehel and Rupert Russell.)

In contrast to the neuraminidase activity of the NA proteins of influenza A and B viruses (see Neuraminidase section), HEF has esterase activity, which cleaves off an acetyl group at position 9 of the neuraminic (sialic) acid receptor, eliminating the ligand (for review, see (644)). This activity is important for entry of the virus, implying a role in releasing the incoming virus from the receptor so that the uncoating process can begin.⁶⁸⁸ Thus, in addition to receptor-binding (hemagglutination) and fusion activities, the molecule also has esterase activity, hence the name HEF. Although there is only about a 12% sequence identity between HAs and HEF, the overall structure of the molecule is similar, as was shown by x-ray crystallographic analysis.⁵⁶⁹ Even more surprising are structural and sequence similarities between the esterases of influenza C viruses and some coronaviruses.⁷⁵⁸

The M2 Protein

The M2 protein of influenza A viruses is a tetrameric type III (lacking a signal peptide sequence) integral membrane protein. It has a short ecto-domain, a transmembrane domain, and a cytoplasmic domain with palmitate and phosphate modifications (for review, see (531,534)). M2 has been shown to

possess ion channel activity, and its major role is thought to be that of conducting protons from the acidified endosomes into the interior of the virus to dissociate the RNP complex from the rest of the viral components, thus facilitating the uncoating process (see earlier section on Fusion and Uncoating). The structural and genetic analysis of the M2 protein has revealed that the ion channel is acid gated (but not voltage gated) and highly selective for H^+ ions.^{86,100,453,454,485} The structures of the transmembrane regions of M2 and of those that include the cytoplasmic sequences reveal a good understanding of the mechanism of proton conductance, which is controlled by the histidine-37 and tryptophan-41 cluster.^{1,79,291,482,589,599,643} The transmembrane region, when viewed from the top, shows four helices that sit at an angle in the lipid bilayer, forming a pore (Fig. 40.11). Structural studies on M2 in complex with adamantane drugs indicate two potential sites of interaction. In the x-ray structure, a single drug molecule binds to the core of the pore.⁶⁴³ In contrast, the NMR structure shows four drug molecules binding to the lipid-exposed surface of the channel close to the cytoplasmic ends of the helices.⁵⁸⁹ More recent data confirm the existence of these two interaction sites and propose that both drug-binding mechanisms may have physiologic

FIGURE 40.9. Model for juxtaposition of viral and endosomal membranes resulting in formation of a fusion pore and release of ribonucleoproteins (RNPs). Structures of influenza virus hemagglutinins in their postfusion state modeled into a possible fusion intermediate (A) and into a fusion pore (B). The fusion peptides are shown inserted into the endosomal membrane, while the trans-membrane domains remain anchored in the viral membrane. Note the large conformational changes of the ecto- and fusion domains when compared to their prefusion structures (see Figs. 40.7 and 40.8). The small spheres (pink) on the fusion peptide denote glycines that may mediate helix interactions and the small squares (blue) denote glutamates that may be responsible for the pH dependence of the fusion peptide penetration into lipid bilayers. Following the formation of a pore, the RNPs are released from the interior of the virus particle into the cytoplasm, completing the uncoating process. (Courtesy of Lukas Tamm.)

significance.^{79,342} The structure and the precise function of the extracellular portion of the M2 protein remain to be resolved. This external portion of M2 has been considered as the basis of a universal influenza virus vaccine approach because the M2 protein maintains a highly conserved sequence over long periods of time.⁵⁹⁰

The ion channel activity of M2 has also been implicated in stabilizing HAs from premature low pH transitions in the trans-Golgi network, but this second function may only come into play for viruses carrying highly acid-sensitive HAs.¹⁰⁴ This is the case for H5 and H7 HAs, which have a multibasic cleavage site that can be cleaved by ubiquitous proteases and are therefore more susceptible to a premature low pH-induced conformational change. Further functions attributed to the M2 protein include roles in particle morphology,^{231,310,564,571}

genome packaging,^{231,310,432} membrane scission⁵⁷² (see Assembly and Release), and inhibition of autophagy.²⁰⁵

Influenza Virus Transcription and Replication Overview

After uncoating, the viral ribonucleoproteins (vRNPs) are transported into the nucleus and the incoming negative-sense viral RNAs (vRNAs) are transcribed into mRNA by a primer-dependent mechanism. These mRNA products are incomplete copies of the vRNA templates and are capped and polyadenylated, unlike vRNA. Replication occurs via a two-step process. A full-length, positive-sense copy of the vRNA is first made, which is referred to as complementary RNA (cRNA), and is in turn used as a template to produce more vRNA (Fig. 40.12).

FIGURE 40.10. Crystal structure of anti-body CR8020 bound to the H3 hemagglutinin. CR8020 binds an epitope on the hemagglutinin (HA) stem and has broad neutralizing activity against multiple group 2 influenza A viruses, including H3, H7, and H10. One monomer from the HA trimer is depicted in yellow and green (HA1 and HA2 subunits, respectively) and CR8020 is colored blue and cyan (heavy chain and light chain, respectively). N-linked carbohydrates are represented as pink van der Waals spheres. See (158) for details. (Courtesy of Damian Ekiert and Ian Wilson.)

FIGURE 40.11. Structure of the tetrameric M2 ion channel. **A:** As seen from the top, four helices sit at an angle in the lipid membrane forming a pore. The backbone structure was determined by solid-state nuclear magnetic resonance (NMR) spectroscopy of the aligned bilayers. The histidine 37 and the tryptophan 41 side chains form the bottom of the pore in the closed state at neutral pH. For details see (485). (Courtesy of Tim Cross.) **B:** X-ray structure of the transmembrane section of the M2 proton channel. The protein backbone is shown as a cartoon, viewed from across the viral membrane (lipid molecules and one of the monomers are hidden). Cyan spheres represent crystallographically resolved water molecules, which are stepping stones in possible proton conduction pathways. The three most important groups of side chains (the Val27-valve [blue], the His37-box [orange], and the Trp41-basket [magenta]) are shown in sticks. The three-dimensional density of water at 37°C, calculated from molecular dynamics simulations, is drawn as a white contour. See (1) for details. (Courtesy of Giacomo Fiorin.)

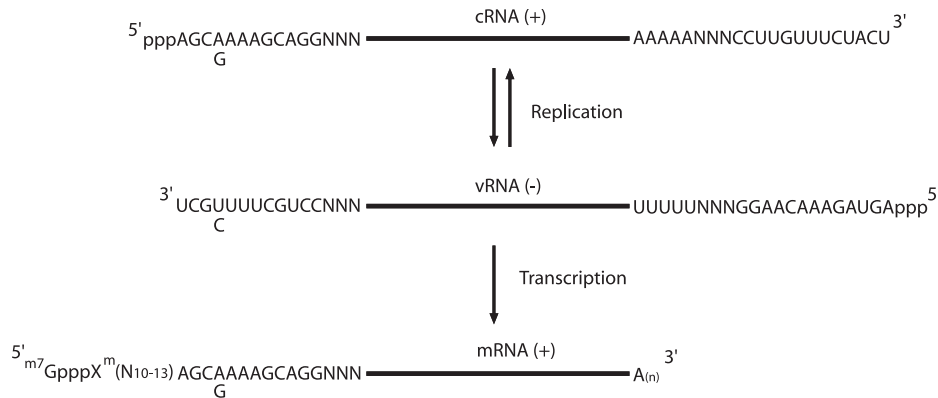

FIGURE 40.12. Influenza virus RNA synthesis. The incoming negative-sense RNA is shown in the middle with the conserved noncoding sequences at either end, adjacent to the segment-specific nucleotides (NNN). The polyadenylation signal consisting of a poly-uridine stretch is at the 5' end of the viral RNA (vRNA). The messenger RNA (mRNA) derives its cap and 10 to 13 5' nucleotides from host mRNAs and has a 3' poly(A) tail. The complementary RNA (cRNA) is an exact positive-sense copy of the incoming virion vRNA. The variation at position 4 in the 3' vRNA noncoding region is indicated.

Nuclear Import of Ribonucleoproteins

One of the characteristics of the influenza virus life cycle, and one that is unusual for an RNA virus, is its dependence on nuclear functions. All viral RNA synthesis occurs in the nucleus, and the trafficking of the viral genome into and out of the nucleus is a tightly regulated process (reviewed in (54,127)). The eight influenza virus genome segments never exist as naked RNA but are associated with four viral proteins to form vRNP complexes. The major viral protein in the RNP complex is the nucleocapsid protein (NP), which coats the RNA. The remaining proteins are the three polymerase proteins (PB1, PB2, and PA), which bind to the partially complementary ends of the viral RNA, creating the distinctive panhandle structure.²⁹⁰ These RNPs (10 to 20 nm wide)^{115,419} are considered too large to allow for passive diffusion into the nucleus and therefore, once released from an incoming particle, they must rely on an active nuclear import mechanism. All proteins in the RNP complex possess nuclear localization signals (NLSs), which mediate their interaction with the nuclear import machinery.^{320,456,470,483,625,702,720} However, it is the signals on NP that have been shown to be both sufficient and necessary for the import of viral RNA^{73,126,496,503} (e-Fig. 40.11).

NP INTERACTIONS WITH KARYOPHERIN α

The transport of proteins across the nuclear membrane is an energy-driven process that is initiated upon recognition of an NLS-containing cargo protein by members of the karyopherin α (also called importin α) family. Karyopherin α binds directly to the NLS and then recruits karyopherin β into a trimeric complex, which docks at the nuclear pore (e-Fig. 40.12). Prior to the identification of a definitive NLS within NP, the human homolog of yeast SRP-1 was identified as an NP-interacting partner.⁴⁹⁷ This uncharacterized protein was subsequently identified as karyopherin $\alpha 1$ and NP was also shown to interact with another family member, karyopherin $\alpha 2$.⁴⁹⁶ The minimal karyopherin α -binding site was used to identify the unconventional NLS in NP, so named because it does not contain a cluster of basic residues.⁷⁰² As described earlier,¹²⁶ this NLS has been shown to be essential for RNP import, and this implicates

karyopherin α as a critical component of RNP nuclear import. Interestingly, the NP NLS-binding site on karyopherin α is distinct from that of classical NLS-containing proteins.^{126,437} One could postulate that this serves to avoid competition for karyopherin α binding with host proteins and may explain the use of an unconventional NLS. There is also evidence that differential interactions with human versus avian karyopherin α proteins may determine species specificity of influenza viruses.^{197,198}

The Viral Ribonucleoprotein Template

Each viral RNA segment exists as an RNP complex in which the RNA is coated with NP and forms a helical hairpin that is bound on one end by the heterotrimeric polymerase complex (reviewed in (554)). NP is an arginine-rich protein and has a net positive charge (at pH 6.5), which reflects its RNA-binding activity and its primary role in encapsidation (reviewed in (541)). The RNA/NP interaction is thought to be mediated by the positively charged residues on NP and the negatively charged phosphate backbone of the RNA, and thus there is no apparent sequence specificity to the interaction.^{30,161} The RNA within the influenza virus RNP also remains sensitive to digestion with RNase,¹⁴⁷ supporting the model that the RNA is wrapped around the outside of the NP with its bases exposed so that they can be accessed by the polymerase without disrupting the RNP structure.³⁰ Approximately 24 nucleotides of RNA are bound by each NP monomer,⁵⁰² and NP also has homooligomerization properties,⁵⁴⁷ which adds a higher-order structure to the RNP complex. This is maintained even in the absence of RNA^{147,576} and has been shown to be crucial for maintaining the RNP in a transcriptionally active form.^{83,160} Crystal structures of NP show that it is composed of a head domain and body domain and that a flexible tail loop mediates oligomerization.^{481,745} A potential RNA-binding groove, which is highly positively charged, has been identified between the head and body domains.⁷⁴⁵ Structural data based on electron microscopy also provide evidence that NP makes direct contact with the bound polymerase complex on the RNP^{13,113,419} (e-Fig. 40.13A), which may reflect the previously reported interaction of free NP with both PB1 and PB2.⁴¹ Detailed mutagenesis of conserved

residues in NP indicates regions that are involved in genome replication/transcription and also genome packaging.³⁸⁸

The RNA Polymerase Complex

The influenza virus RNA-dependent RNA polymerase is a 250-kD complex of three proteins: PB1, PB2 and PA.⁵⁹ A three-dimensional image of the complex obtained by electron microscopy indicates that the three subunits are tightly associated to form a compact structure^{13,669} (e-Fig. 40.13B). Protein interaction studies have shown that PB1 binds to both PA and PB2, through its N- and C-terminal domains, respectively,^{228,492} and that the N-terminus of PA interacts with PB2.²⁶⁸ The details of how the newly synthesized polymerase is assembled are still under debate. One model proposes that PB1 and PA enter the nucleus as a dimer through interactions with RanBP5 and then bind to PB2, which is imported independently via a karyopherin α interaction.^{135,183,300,555,661} This is supported by fluorescent spectroscopy data in live cells.²⁹⁵ However, another model suggests that PB1-PB2 dimer is transported into the nucleus (via the chaperone Hsp90) and that PA traffics separately.⁴⁶⁵ It has also been shown that vRNA can bind to the PB1-PA dimer *in vitro* prior to PB2 binding as well as to the preformed trimeric complex.¹³⁶

THE PB1 PROTEIN

The PB1 protein catalyzes the sequential addition of nucleotides during RNA chain elongation⁵⁹ and contains the conserved motifs characteristic of RNA-dependent RNA polymerases.⁴² The active site for the polymerization activity is an S-D-D motif at positions 444 to 446,⁴² but we currently lack structural information for this region. In fact, only small regions encompassing the extreme N- and C-termini of PB1 have been crystallized in complex with portions of PA and PB2, respectively. Two studies have provided x-ray structures of either residues 1 to 81 or 1 to 25 of PB1 in complex with the C-terminal portion of PA,^{265,490} and it has been shown that synthetic peptides corresponding to this region of PB1 can compete with full-length PB1 for PA binding and inhibit virus replication.²¹⁹ The PB1 C-terminus (residues 678 to 757) has been shown to mediate an interaction with residues 1 through 37 of PB2, and structural analysis of this complex indicates that both peptides form three helices whose folding is dependent on the presence of each partner.⁶⁴⁶ PB1 is also responsible for binding to the terminal ends of both vRNA^{226,377} and cRNA²²⁷ for initiation of transcription and replication.

THE PB2 PROTEIN

The PB2 protein plays a critical role in the initiation of transcription as it is responsible for binding the cap on host pre-mRNA molecules.^{43,674} Despite earlier discrepancy in the position of the binding site, it has now been shown that a domain encompassing PB2 residues 318 to 483 is sufficient for cap binding²³⁶ and confirms the findings of a mutagenesis study that identified two aromatic residues (F363 and F404) as being important for the interaction.¹⁷¹ An x-ray structure of this minimal domain bound to cap analog m⁷GTP reveals that the cap is sandwiched between phenylalanine 404 and histidine 357 in a mode similar to that described for other cap-binding proteins, although the involvement of a histidine is unique.²³⁶ In fact, in influenza B and C virus PB2 proteins, the histidine is replaced with a more traditional tryptophan.

Both NMR and x-ray structures of the C-terminal domain (aa 678 to 759) of PB2 have been obtained, the latter in complex with karyopherin $\alpha 1$.⁶⁶¹ Within this domain the authors report the presence of a bipartite nuclear localization signal, and in the co-crystal it is shown how this region unfolds to allow for interaction with karyopherin $\alpha 1$. PB2 has also been shown to localize to the mitochondria, and this is determined by an N-terminal mitochondrial-targeting signal.⁸¹ However, avian influenza viruses have a polymorphism in this signal, so it appears that mitochondrial localization of PB2 is unique to human influenza viruses.²²⁹ Finally, as well as interacting with PB1 via its N-terminus (see PB1 section earlier), PB2 is also reported to interact with PA; however, the region of PB2 involved has not yet been defined.²⁶⁸ PB2 also participates in genome replication as mutations affecting this activity but not transcription have been reported.²¹⁵

THE PA PROTEIN

Until recently, the specific function of PA was unknown, but crystal structures of the N-terminal domain revealed that the endonuclease activity of the polymerase, which is required to generate the capped primer, resides in the PA protein.^{139,752} Previous work had mistakenly attributed this function to the PB1 protein. In the structure, the fold and position of the active site identifies the PA endonuclease as a member of the PD-(D/E)XK family of nucleases. The catalytic site involves residues His 41, Glu 80, Asp 108, Glu 119, and Lys 134 and harbors two Mn⁽²⁺⁾ ions.^{124,139} Mutation of these residues abolishes the transcriptional activity of the trimeric polymerase but replication activity is unaffected, confirming the specific role of the endonuclease in viral transcription.^{124,752} PA does, however, participate in genome replication as mutations affecting this process have been described.^{179,294} In addition to encoding nuclease function, the N-terminus of PA (aa 1 to 100) is also reported to be involved in an interaction with PB2,²⁶⁸ while the C-terminus makes contact with PB1. Structures of PA residues 257 to 716 show this region forming a “dragon-like head” with the N-terminal peptide of PB1 inserted into the mouth.^{265,490} Another function ascribed to PA is that it possesses proteolytic activity.⁵⁸² Two residues, S624²⁵⁵ and T157,⁵²⁵ have been reported to be involved in the proteolytic function, although viruses containing mutations at position 157 appear to be more severely affected than those mutated at position 624.^{294,670} PA has also been shown to be a target for casein kinase II and to be phosphorylated at serine and threonine residues.⁵⁸³

The vRNA Promoter

All influenza virus RNA segments contain noncoding sequences at their 5′ and 3′ ends, which flank the coding region. Some of this sequence is segment specific,⁷⁶⁶ but the terminal ends are conserved between all segments in all influenza viruses. These conserved 13 nucleotides at the 5′ end and 12 nucleotides at the 3′ end display partial and inverted complementarity, which led to the proposal of a panhandle structure created by base-pairing of the 5′ and 3′ ends.^{138,565} This is supported by cross-linking experiments that demonstrated a circular configuration for virion RNAs²⁹⁰ as well as by more recent structural analysis.^{19,419} Studies using *in vitro* transcription of model RNA templates or reporter gene expression *in vivo* have shown that both 5′ and 3′ terminal ends are necessary for promoter activity and that base-pairing is required (reviewed in (177,475)). Furthermore,

it has been demonstrated that the polymerase can interact with both 5' and 3' ends and that the binding affinity decreases when the duplex is disrupted.^{182,226,240,373,664} These data define the vRNA promoter as a double-stranded element formed by the conserved 5' and 3' terminal ends of the vRNA molecule.⁴⁸⁷ While the need for base-pairing is clear, several models for the secondary structure of the promoter have been proposed based on mutational analyses (e-Fig. 40.14). The original panhandle model predicts extensive Watson-Crick base-pairing, whereas the RNA-fork model proposes that the extreme termini remain single stranded.^{181,182,332} The corkscrew model suggests that these single-stranded regions in fact base-pair within themselves to form 5' and 3' hairpin loops.¹⁷⁶ The presence of both 5' and 3' stem-loops has been shown to be critical for endonuclease activity, and the 5' stem-loop is also required for polyadenylation.^{364,365,545} This favors a model where the stem-loop structures are involved in binding and stabilizing the polymerase complex.⁶⁴

Initiation of Messenger RNA Synthesis

Influenza virus mRNA synthesis is dependent on cellular RNA polymerase II activity. This is because it requires a 5'-capped primer, which it steals from host pre-mRNA transcripts, to initiate its own mRNA synthesis. This process is known as cap snatching and involves the cap-binding function of the PB2 protein and endonuclease function of the PA protein. The

initiation of transcription commences with binding of the 5' end of the vRNA to the PB1 subunit (Fig. 40.13). This induces an allosteric change in the polymerase, which allows the PB2 protein to recognize and bind the cap structure on host pre-mRNAs^{106,377} (reviewed in (170)). The change in the polymerase also increases its affinity for the 3' vRNA end, which is bound by PB1. Binding of the 3' terminus stabilizes the polymerase complex⁶⁴ and also serves to activate the endonuclease function.^{106,240,364,377} However, in contrast to this model, one report states that endonuclease activation only requires a bound 5' end,⁵⁵¹ the difference being that this study used capped RNA fragments with "CA" 3' termini as primers. Primers with this specific end have previously been shown to be used preferentially for transcription initiation in infected cells.^{32,604} Another study indicates that both primer-binding and endonuclease activities are greatly enhanced when the polymerase binds simultaneously to the 5' and 3' ends (i.e., in a preformed duplex).³⁷³ Endonuclease activation leads to cleavage of the bound pre-mRNAs. This occurs approximately 10 to 13 nucleotides from their 5' caps, usually after a purine residue.^{32,537} Transcription is then initiated by the addition of a "G" residue to the primer, directed by the penultimate "C" nucleotide at the 3' end of the vRNA template,³² although in some instances the incorporation of a "C" that is directed by the "G" at position 3 in the vRNA has also been observed.¹⁸¹ Unlike influenza viruses, Thogoto viruses lack host-derived sequences at the 5' end of their capped mRNAs.⁷¹⁹ RNA chain elongation is

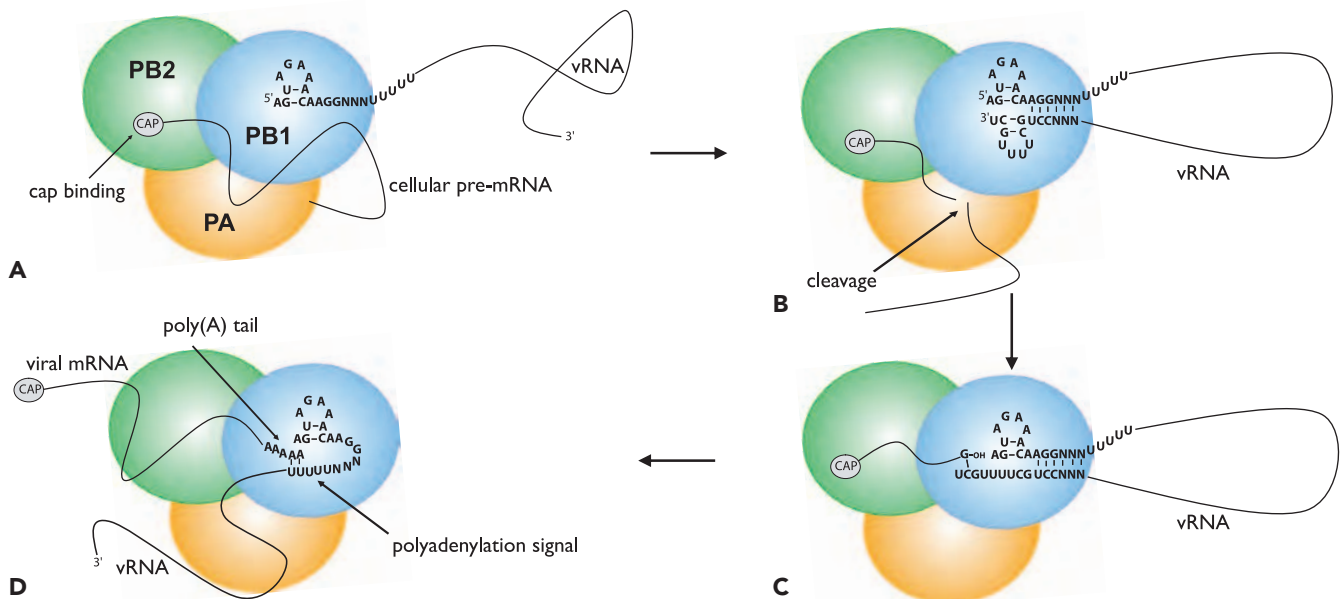

FIGURE 40.13. Proposed model for transcription initiation, elongation, and polyadenylation of influenza virus messenger RNA (mRNA). **A:** The 5' end of the viral RNA (vRNA) is shown in the corkscrew configuration bound to the polymerase basic 1 (PB1) subunit of the polymerase complex. This activates the cap-binding activity of the PB2 subunit. **B:** The 3' end of the vRNA binds to PB1 and forms a duplex with the 5' end. The endonuclease activity of the polymerase acid (PA) then cleaves the pre-mRNA 10 to 13 nucleotides downstream of the cap structure. **C:** A guanosine residue is added to the 3' end of the capped primer and base-pairs with the penultimate C residue at the 3' end of the vRNA. This initiates transcription and chain elongation is catalyzed by the polymerase function of the PB1 subunit. **D:** During elongation the cap detaches from the polymerase. However, the 5' end of the vRNA remains bound while the template vRNA is read in a 3' to 5' direction and consequently the polymerase is unable to read beyond the poly-uridine stretch due to steric hindrance. This causes it to stutter and a poly(A) tail is added to the 3' end of the nascent mRNA. (Adapted from Fodor E, Brownlee GG. Influenza virus replication. In: Potter CW, ed. *Influenza*. Amsterdam, The Netherlands: Elsevier, 2002:1–29.)

catalyzed by the polymerase function of PB1 and continues until a stretch of uridine residues is encountered approximately 16 nucleotides before the 5' end of the vRNA.^{383,407,566} This is the signal for polyadenylation (Fig. 40.13).

Polyadenylation

Unlike host cells, which use a specific poly(A) polymerase for generating the poly(A) tail on mRNA transcripts, polyadenylation of influenza virus mRNAs is catalyzed by the same polymerase that is used for transcription. This activity is dependent on an uninterrupted stretch of five to seven “U” residues and the adjacent double-stranded region of the vRNA promoter.^{383,407,566} The current model proposes that the 5' end of the vRNA remains bound to the polymerase during elongation while the template is threaded through in a 3' to 5' direction (Fig. 40.13). When the polymerase nears the 5' end to which it is bound, it is blocked by steric hindrance and consequently it stutters on the preceding stretch of uridines, which it repeatedly copies to produce a poly(A) tail.^{182,240,539,765} In support of this model, mutations introduced into the 5' end of the vRNA that prevent or weaken polymerase binding have been shown to also inhibit polyadenylation.^{180,540,545,546} The polyadenylation signal is vital for gene expression as replacement of the uridines with adenosines has been shown to result in transcripts with poly(U) tails, which fail to be properly exported from the nucleus.⁵³⁸

Splicing

Members of the *Orthomyxovirus* family can extend the coding capacity of their genomes by producing two proteins from one gene via an alternative splicing mechanism. Genome segments that encode proteins from both spliced and unspliced mRNA transcripts are segments 7 and 8 of influenza A virus,^{358,360} segment 8 of influenza B virus,⁶³ segments 6 and 7 of influenza C virus,^{468,741} segment 6 of Thogoto virus,³³⁹ and segment 7 of isavirus⁴⁰ (see Genome Structure and Organization section). The primary transcripts from these segments have 5' and 3' splice sites, which (more or less) fit the consensus sequence for the exon/intron boundaries of cellular transcripts. This, combined with the fact that splicing can be demonstrated in the absence of any viral proteins,^{357,359} indicates that the virus is using the cellular splicing machinery. However, unlike cellular splicing, which is extremely efficient, splicing of viral mRNA has to be relatively inefficient because proteins must be expressed from both spliced and unspliced mRNAs. In influenza virus-infected cells, splicing is tightly regulated such that the steady-state level of spliced viral transcripts is only 10% that of the unspliced viral transcripts.^{356,360} These control mechanisms may act on several different levels. The rate of nuclear export of the unspliced transcript is certainly crucial as this determines its availability for splicing. It has been proposed that the NS1 protein inhibits both the splicing and nuclear export of NS1 transcripts via negative feedback,^{8,209} but contradictory reports⁵⁵⁹ suggest that alternative mechanisms may exist for regulating splicing of viral transcripts. Potentially these may involve *cis*-acting sequences in the NS1 transcript that negatively control the rate of splicing.^{7,474} Strangely, the influenza C virus NS1 protein has been reported to up-regulate viral mRNA splicing.⁴⁵⁸ Splicing of the influenza A virus M1 transcript is controlled by the aforementioned rate of nuclear export⁶⁷⁵ as well as by the viral polymerase and a cellular splic-

ing factor, SF2/ASF. The polymerase determines the time at which splicing (and hence production of M2) occurs, and SF2/ASF is required to activate splicing.^{605,606}

Replication Products: cRNA and vRNA

Full-length copies of the incoming vRNA have to be made, and these positive-sense cRNAs serve as templates for the synthesis of new negative-sense genomic vRNA. *In vitro* evidence suggests that the *de novo* initiation mode for vRNA synthesis may occur via terminal initiation and elongation, whereas for cRNA synthesis it involves internal initiation and realignment.¹³⁷ This is a primer-independent model; however, a primer-dependent mode of vRNA initiation has also been proposed.⁵²⁸ The cRNA promoter is complementary to the vRNA promoter and has also been reported to assume a corkscrew configuration, albeit with subtle differences.^{18,129,519,766} This variation has been implicated in determining whether or not the endonuclease function of the polymerase is activated and therefore may play an important regulatory role.³⁶⁶

The Switch from Transcription to Replication

The vRNA serves as a template for both mRNA and cRNA synthesis, and yet the means of initiation and termination for the generation of these two molecules are quite different. In contrast to the primer-dependent mechanism of initiation of mRNA synthesis, initiation of cRNA synthesis occurs without a capped primer and cRNA molecules are full-length copies of the vRNA and thus are not prematurely terminated and polyadenylated as are mRNAs. The different initiation and termination reactions therefore have to be coordinated, but exactly how the polymerase switches between these two modes is not well understood. It has been proposed that the transcription-competent polymerase is structurally different from the replication-competent polymerase, and support for this theory comes from evidence that different domains of PB1 are involved in binding vRNA versus cRNA and that PA is more critical for binding the cRNA than the vRNA promoter.^{227,412} One obvious difference is that the cap-binding and endonuclease functions of PB2 and PA are not required when the polymerase is in replication mode.

In contrast to mRNAs, newly synthesized cRNAs and vRNAs are encapsidated, and it has been proposed that the availability of soluble NP (i.e., not associated with RNPs) controls the switch between mRNA and cRNA synthesis. This hypothesis arose from the observation that replication is dependent on *de novo* protein synthesis, which means that the incoming RNPs are only capable of transcription.²⁶³ Indeed, free NP has been shown to be required for production of full-length cRNA (antitermination),³³ and this is consistent with data from temperature-sensitive (ts) NP mutants,^{345,435,598} which show that cRNA but not mRNA synthesis is affected at the nonpermissive temperature. However, this model has been challenged by a report demonstrating that overexpressed NP does not promote replication.⁴⁵⁷ Another study disputes the existence of a switch, rather suggesting a stabilization role for NP and the polymerase.⁶⁹⁴ It claims that the incoming polymerase is able to synthesize both mRNA and cRNA,⁶⁹⁰ but until there is a sufficient pool of polymerase and NP to encapsidate the cRNA, it is degraded and therefore at early times postinfection there is a bias toward mRNA accumulation. Also, requirements for higher nucleotide concentrations

to initiate cRNA synthesis may determine the timing of transcription versus replication.⁶⁹³ Furthermore, the accumulation of NEP/NS2 is associated with a decrease in transcription and an increase in replication, suggesting a regulatory role.^{74,560} Interestingly, NEP/NS2 is also required for the generation of small viral RNAs (svRNAs), which have been implicated in the initiation of vRNA synthesis.⁵²⁸ The svRNAs are 22 to 27 nt in length and correspond to the 5' end of each viral RNA segment. These segment-specific svRNAs are needed for vRNA but not cRNA synthesis, so according to this model the polymerase is in replication mode when these svRNAs are present. It has also been proposed that the switch from transcription to replication is the result of accumulation of a newly synthesized free polymerase complex, which enhances cRNA to vRNA synthesis (and vice versa) over mRNA synthesis.³²² The role of host factors in regulating influenza virus replication, including posttranslational modification of viral proteins, should also not be excluded.^{51,323,392,427,449,450}

Regulation of Viral Gene Expression

Early studies have provided evidence for temporal regulation of viral gene expression,^{263,624} but the mechanism(s) is still unresolved. Disproportionate accumulation of mRNAs from the eight segments has been observed, but whether this represents specific up-regulation of transcription for these segments^{164,260} or reflects different rates of vRNA synthesis^{597,624} or RNA stability is unclear. Suffice to say that the synthesis of NP and NS1 mRNAs and protein is favored at early stages, whereas the synthesis of HA, NA, and particularly M1 mRNAs and proteins is delayed.^{260,263,597,624} This differential expression is mirrored by the roles these proteins play at different points in the virus life cycle. As discussed earlier, NP is required for replication, and NS1 plays a crucial role in combating the host immune response; thus, both these proteins are needed early in the virus life cycle. M1 has been found to inhibit viral transcription,^{527,713} which demands its delayed expression, and at later stages M1 accumulation probably dictates the arrest of viral mRNA synthesis. M1 is also involved in the export of RNPs from the nucleus,⁴²⁰ which must only occur once replication is complete.

Another control mechanism for differential gene expression resides in the vRNA promoter. A natural variation is found at position 4 from the 3' vRNA end in an otherwise totally conserved region. The PB1, PB2, and PA RNA segments have a "C" at this position, while the remaining segments usually have a "U." The C4-containing promoter is associated with a down-regulation in transcription and an up-regulation in replication compared to the U4 promoter,³⁷⁰ which correlates with the lower amounts of polymerase mRNAs and proteins found in infected cells.^{263,624} A structural analysis of the C4 and U4 promoters has revealed differences that may alter their interaction with the polymerase and thereby regulate gene expression.³⁷²

As observed with many other viruses, influenza virus gene expression is also controlled at the level of translation. This is achieved via numerous mechanisms and results in the selective translation of viral genes and suppression of host protein synthesis (reviewed in (200,692,743)). These mechanisms include (a) degradation of host pre-mRNAs following cleavage (due to cap-snatching), (b) inhibition of host mRNA processing, (c) degradation of cellular RNA polymerase II, and (d) preferential translation of viral mRNA transcripts. Several of these processes involve the influenza virus NS1 protein. The NS1-mediated

effect on mRNA processing is discussed in a later section (see The Actions of Influenza Virus Nonstructural Proteins on the Host Cell). NS1 is also involved in the specific translational enhancement of viral mRNAs through its association with the 5' noncoding region of viral mRNA transcripts and with cellular proteins involved in translation initiation.^{11,76,520} These include the translation initiation factor eIF4GI and poly(A)-binding protein 1, and it has been proposed that this protein complex acts to specifically recruit ribosomes to the 5' end of viral mRNA transcript. Another cellular protein that may play a role is GRSF-1, an RNA-binding protein that has been reported to interact with the 5' end of the NP transcript and to stimulate the specific translation of a template driven by the NP 5' non-coding region in a cell-free translation system.^{326,521} Whether this interaction is relevant *in vivo* remains to be determined.

An interesting model explaining the selective translation of viral mRNAs has been proposed suggesting that the viral polymerase complex remains associated with the viral mRNA transcript in the cytoplasm. It is thought that this interaction eliminates the need for complex formation with eIF4E. As eIF4E is inactivated in influenza virus-infected cells,¹⁷² this would explain the selective translation of viral transcripts over cellular transcripts. Other components of the translation machinery, such as eIF4A and eIF4G, are required for influenza viral protein translation.⁷⁴² Although this model is compelling in its simplicity, this mechanism is questioned by the finding that viral mRNAs in the cytoplasm are devoid of viral polymerase but are associated with cellular cap-binding proteins, including eIF4E.³⁹ Clearly, further investigation is required to explain the selective translation of viral transcripts in infected cells.

An additional host shut-off mechanism is controlled by the viral polymerase at the level of host transcription. It has been shown that the influenza virus polymerase interacts with the C-terminal domain of the large subunit of cellular RNA polymerase II¹⁶⁷ and that this interaction mediates the degradation of RNA polymerase II at late times postinfection.^{568,691} This may play a role in viral pathogenicity because attenuated influenza viruses have been shown not to induce RNA polymerase II degradation.⁵⁶⁷

Virus Assembly and Release

Nuclear Export of Ribonucleoproteins

ASSOCIATION OF RNP WITH M1

Following virus replication, newly formed RNP complexes are assembled in the nucleus from where they are exported into the cytoplasm. Two viral proteins, the matrix protein (M1) and the nuclear export protein (NEP/NS2), are involved in directing the nuclear export of RNPs (reviewed in (54,127)). Our present understanding of this process indicates that M1 associates with RNPs in the nucleus and may actually promote the formation of RNP complexes.²⁹³ M1 makes contact with both the vRNA and NP^{31,746} (reviewed in (127,472)), and evidence that M1 also binds to nucleosomes^{210,769} has led to the hypothesis that M1 interactions cause the dissociation of RNP from the nuclear matrix. This agrees with the significant finding that nuclear import of M1 is required for subsequent export of RNP complexes.^{72,420} Furthermore, at high temperatures, heat shock protein 70 is found bound to RNP, which prevents association with M1 and results in a block in RNP export.^{273,580} Recently it has been reported that sumoylation of M1 is essential for its nuclear export function.⁷³²

NEP/NS2 INTERACTS WITH THE CELLULAR EXPORT MACHINERY

Initially these data suggested that M1 alone could control RNP export, but as is the case for import, nuclear export of large molecules involves direct interactions with the cellular export machinery and as yet no such interactions with M1 have been demonstrated. However, NEP/NS2 has been found to interact with the export receptor Crm1⁴⁷⁷ and several nucleoporins.^{91,498} NEP/NS2 also associates with M1,^{4,608,744} so the current model is that an RNP–M1–NEP/NS2 complex is formed in the nucleus and that NEP/NS2 is responsible for recruiting the export machinery and directing export of the complex (e-Fig. 40.15). In support of this role, it has been shown that injection of anti-NEP/NS2 antibodies into the nucleus of infected cells inhibits RNP export,⁴⁹⁸ which is also seen in a system using recombinant virus-like particles lacking NEP/NS2.⁴⁷⁷ A methionine/leucine-rich nuclear export signal (NES) has been identified in the N-terminus of NEP/NS2⁴⁹⁸ and shown to be critical for RNP export and virus growth^{309,477}; however, this NES does not appear to mediate the interaction of NEP/NS2 with Crm1.⁴⁷⁷ Yet treatment with leptomycin B, a Crm1 inhibitor, completely inhibits RNP export in infected cells, which indicates that export does occur in a Crm1-dependent manner.^{162,309,714}

Another viral protein, NP, has also been shown to bind to Crm1¹⁶² and therefore is proposed to play a role in export as well as import. Both this study and another also revealed that RNPs are localized to the periphery of the nucleus after leptomycin B treatment but that M1 and NEP/NS2 retain diffuse nuclear staining.^{162,410} The RNPs were shown to co-localize with nuclear lamins just beneath the nuclear pore complex, which may represent an intermediate step prior to export through the pore.⁴¹⁰ The roles of M1 and NEP/NS2 are obviously called into question by their differing staining pattern compared to RNP,^{162,410} but this could be explained if only a fraction of the total M1 and NEP/NS2 pool was used for export. Nevertheless, it raises the possibility that redundant export mechanisms may exist.

REGULATION OF RNP EXPORT

As discussed earlier, the late expression of M1 determines that export takes place only after a full round of replication has occurred, therefore preventing premature exit of RNPs from the nucleus. Similarly, control mechanisms must also exist to stop the re-entry of RNPs into the nucleus following export. Studies with a temperature-sensitive virus (ts51) showed that when grown at the nonpermissive temperature, this virus is unable to retain its RNPs in the cytoplasm following export.⁷²³ This defect mapped to M1,⁷²⁴ once again demonstrating the vital role of this protein in regulating the nucleocytoplasmic transport of RNPs. It is interesting to note that the NEP/NS2-binding site on M1 maps to the M1 NLS⁴ which suggests that NEP/NS2 may act to mask the NLS on M1 and therefore prevent the complex from re-entering the nucleus. NP is also proposed to cause the cytoplasmic retention of RNPs by binding to filamentous actin and thereby anchoring the RNPs in the cytoplasm.¹⁴⁰ All these processes are likely to be regulated at some level, and protein modification by phosphorylation is probably involved as several studies have reported alterations in M1, NEP/NS2, and NP trafficking in the presence of kinase inhibitors.^{70–72,536,553,724}

RNP EXPORT IN INFLUENZA B AND C VIRUSES

Few studies concerning export in influenza B and C viruses have been performed, but it has been shown that as with influ-

FIGURE 40.14. Budding influenza virus particles. Electron micrograph thin section image of influenza virus particles budding from the apical surface of an infected cell. (Courtesy of Yi-ying Chou.)

enza A viruses, the NEP/NS2 proteins possess nuclear export activities.⁵¹⁸ They have both been shown to interact with Crm1 (and a subset of nucleoporins), and NES motifs have been defined in each protein. Interestingly, the influenza C virus NES is composed of two separate leucine-rich domains, both of which are required for full activity.⁵¹⁸ In contrast to influenza A virus where M1 acts as a bridge between NEP/NS2 and the RNP complex, the influenza B NEP/NS2 has been proposed to bind directly to RNP as well as to M1,³⁰⁴ which suggests that the model for export of influenza B virus RNPs may be slightly different.

The Site of Virus Assembly and Budding

Influenza viruses assemble and bud from the apical plasma membrane of polarized cells (e.g., lung epithelial cells of the infected host)⁵³ (reviewed in (573,587)) (Fig. 40.14). This asymmetrical process (i.e., apical vs. basolateral) is thought to have an important role in viral pathogenesis and tissue tropism in that viruses that bud from the internal cell surface (e.g., Marburg virus) tend to cause systemic disease, whereas viruses such as influenza virus that bud from the external cell surface generally have a more restricted tissue tropism.¹⁷³ The influenza virus HA, NA, and M2 have all been shown to localize to the apical surface of polarized cells when expressed alone,^{296,321,574} and apical sorting signals have been identified within the transmembrane domains of HA and NA.

THE M1 PROTEIN

M1 is the most abundant virion protein and lies just beneath the lipid envelope where it is believed to make contact with the cytoplasmic tails of the glycoproteins and with the RNPs, thereby forming a bridge between the inner core components and the membrane proteins (reviewed in (471,587)). Structural analyses indicate that the M1 protein consists of two globular helical domains that are linked by a protease-sensitive region.^{14,257,595} Rods (6 nm in length) corresponding to M1 monomers have been observed by negative stain electron microscopy of virions with one end in contact with the membrane and the other end pointing toward the interior of the particle.⁵⁷⁵ These rods form an ordered structure consistent with the homo-oligomerization properties of M1^{80,764} and are arranged such that the positive and negatively charged residues are on opposite sides of the oligomer.^{14,257} Several reports have documented the ability of M1 to associate with lipid membranes^{163,575,759} (reviewed in (471,587)),

and as mentioned previously (see section on Nuclear Export of Ribonucleoproteins), M1 interacts with both RNP and NEP/NS2. M1 also interacts with the cytoplasmic tail of M2.⁸⁷ Therefore, it is proposed that M1 plays a vital role in assembly by recruiting the viral components to the site of assembly at the plasma membrane.

Assembly of Viral Components

Following synthesis on membrane-bound ribosomes, the three integral membrane proteins, HA, NA, and M2, enter the ER where they are folded and glycosylated (except for M2) and where HA is assembled into a trimer and NA and M2 into tetramers (reviewed in (141)). They are subsequently transported to the Golgi apparatus where cysteine residues on HA and M2 are palmitoylated in the *cis*-Golgi network.^{635,647,681–683} For those HAs that have a multibasic cleavage site (i.e., some H5 and H7 subtypes), furin cleavage of HA into HA1 and HA2 subunits may occur in the *trans*-Golgi network.⁶⁴² From here HA, NA, and M2 are all directed to the virus assembly site on the apical plasma membrane via their apical sorting signals. The signals for HA and NA have been described to reside in their transmembrane domains (TMDs).^{26,350,393} The TMDs of HA and NA also contain the determinants for association with lipid rafts^{26,393} (reviewed in (25)). Lipid rafts are nonionic detergent-resistant lipid microdomains within the plasma membrane that are rich in sphingolipids and cholesterol (reviewed in (499)), and examination of the lipid content of purified virus particles indicates that influenza virus buds preferentially from these domains.^{585,760} HA and NA individually also selectively accumulate at and are incorporated into rafts.^{350,586} Although the signals for apical sorting and raft association both lie within the TMD, they are not mutually exclusive (reviewed in (25,472)). Raft association of HA has been shown to be essential for efficient virus replication.⁶⁵⁵ This is thought to be because of a requirement for concentrated “patches” of HA at the plasma membrane, which governs the level of HA incorporation into budding particles and hence affects fusion. A similar explanation holds for raft association of NA, as an optimal amount of NA must be incorporated to allow for efficient virus release.²⁴ In contrast to HA and NA, the majority of M2 protein is excluded from lipid rafts,⁷⁶⁰ which may reflect its low abundance in virus particles. M2 has been shown to bind cholesterol and this property is suggested to target M2 to the raft periphery where it may act to bridge several raft domains.⁵⁹¹ Mutation of the cholesterol recognition/interaction amino acid consensus (CRAC) motif in M2 is reported to affect membrane targeting but not raft association,⁶⁶² and in the context of a recombinant virus it is shown to attenuate the virus *in vivo* but not in tissue culture.⁶⁴¹ There is also evidence that M2 is involved in capturing the RNPs at the assembly site. Experimental evidence for this mechanism was first demonstrated with an influenza B virus that lacked BM2 expression and produced particles devoid of RNPs.³⁰³ Subsequently, mutation or truncation of the influenza A virus M2 cytoplasmic tail has been shown to correspond with decreased incorporation of genome segments into virions.^{231,310,431,432}

In comparison to the integral membrane proteins, relatively little is known about how the remaining viral components reach the assembly site. A long-standing hypothesis is that M1 acts as the master recruiter as dictated by its position between the viral envelope and the RNP core. This is supported

by evidence that the availability of M1 affects the timing of assembly and maturation, as seen with a virus engineered to express reduced levels of protein from the M segment.⁵⁶ This virus showed no defects in virion protein composition but displayed delayed growth kinetics, suggesting that a minimum amount of M1 protein must accumulate before assembly can begin. The association of M1 with the RNP–NEP/NS2 complex is well described (see section on Nuclear Export of Ribonucleoproteins), but the specific interaction of M1 with the membrane-bound glycoproteins has been difficult to prove because of its intrinsic membrane-binding properties and initially resulted in some conflicting reports.^{163,344,759} However, it was noted that in influenza virus-infected cells M1 becomes resistant to extraction with Triton X-100 (a marker for lipid raft association), whereas M1 expressed alone remains soluble.^{6,759} This suggested a role for other viral proteins, and indeed, co-expression of HA and NA together with M1 has been shown to promote raft association of M1.⁶ This requires the TMDs and cytoplasmic tails of HA and NA,^{6,760} and in the absence of the cytoplasmic tails of these two proteins, virus particles have been found to be grossly distorted, which perhaps indicates reduced M1 association.³¹⁷ The hypothetical model therefore proposes that M1 becomes associated with the glycoproteins during their passage through the exocytic pathway and “hitches a ride” to raft domains in the apical membrane, taking the RNP–NEP/NS2 complex with it. However, alternative models have been suggested, and these include the possibility that the M1/RNP complex may use the cytoskeleton to reach the virus assembly site. This is fueled by the finding that both NP and M1 interact with cytoskeletal components.¹⁷ The M1 interaction is dependent on the presence of RNP and is most likely mediated by direct binding of F-actin by NP.^{17,140} However, an intact cytoskeleton has only been found to be necessary for the production of filamentous virus particles,^{563,614} so a specific role in assembly *per se* is debatable, although actin does appear to be involved in the organization of lipid rafts.⁶¹⁴ Finally, there is evidence that NP alone is intrinsically targeted to the apical plasma membrane and associates with lipid rafts in a cholesterol-dependent manner, which suggests that RNPs could reach the assembly site independently of the other viral components.⁸² Recent studies have shown that the Rab11-dependent recycling endosome is critical for the delivery of RNPs to the plasma membrane.^{9,155,451} as is another endosomal protein, human immunodeficiency virus rev-binding protein (HRB), which interacts with NEP.¹⁵⁶

Packaging of Eight RNA Segments

Correct assembly and packaging of a full complement of RNA genome segments is a requirement for a fully infectious virion. The precise mechanism of packaging of the eight viral RNA segments is not well understood, although two different models have been proposed. The first model, the *random incorporation model*, assumes that a common structural feature is present on all vRNAs (vRNPs), which enables them to be randomly incorporated into budding virions. This model is supported by evidence that virions may possess more than eight vRNPs, ensuring the presence of a full complement of eight vRNPs in a significant percentage of virus particles.^{22,166,207} Mathematical analysis of packaging suggests that if eight RNA segments were randomly packaged into budding virions, only 0.24% of released virus particles would be infectious.¹⁶⁶ However, if a

greater number of RNA segments were randomly packaged, then the percentage of infectious particles increases (reviewed in (114)). If 12 RNA molecules are packaged per virion, then approximately 10% of the virus particles would be infectious,¹⁶⁶ a number that is compatible with experimental data ((142) and reviewed in (114)).

The second model, *the selective incorporation model*, suggests that each vRNA segment acts independently, allowing each segment to be packaged selectively. A similar model has been reported for the packaging of the 3 double-stranded RNA (dsRNA) segments of bacteriophage $\phi 6$ (reviewed in (446)) and for the packaging of the 11 dsRNA segments of rotavirus (RV) (reviewed in (433)). This model suggests that each vRNA segment contains a unique “packaging signal” and predicts that every virion possesses a full complement of the eight vRNP segments. There is increasing evidence to support this model. First, the precise number of RNAs packaged in a single virion has been determined by imaging of serially sectioned budding virions using electron microscopy.⁴⁸⁹ Each virion appears to contain exactly eight vRNPs organized in a distinct pattern: one in the center and seven in the surrounding positions. The eight vRNPs are oriented perpendicular to the budding tip. Second, the existence of packaging signals within the noncoding and coding regions at both the 5′ and 3′ ends of the genomic RNAs has been confirmed (e-Fig. 40.16). Coding regions of the NA¹⁹¹; HA⁷¹⁸; NS¹⁸⁹; PB2, PB1, and PA^{390,462}; NP⁵⁰³; and M⁵⁰⁵ segments have all been demonstrated to increase the ability of a reporter sequence to be incorporated within assembling virions. Both the coding and noncoding regions of the packaging signals are relatively conserved compared to other parts of the sequences.^{194,224} Mutations introduced into the packaging signal region of one segment can result in a decrease in packaging efficiency of the segment itself and other segments,^{299,302,391,416,417} suggesting the existence of specific interactions among genomic segments. Interestingly, data also show that efficient packaging of the NS segment does not absolutely require the original sequences of the packaging signal.¹⁹⁰ Segment-specific packaging is hypothesized to occur via specific RNA–RNA or protein–RNA interactions, but exactly how the packaging signals participate during the genome packaging process is yet to be determined. Another piece of evidence supporting the specific packaging model is the generation of a rewired influenza virus carrying the HA packaging signal on the NS segment and the NS packaging signal on the HA segment.²⁰⁸ The modified virus grew well; however, it lost its ability to independently reassort its rewired HA or NS segment with a wild-type virus, indicating that only viruses containing a full complement of all eight packaging signals will grow to high yields. This model is also supported by data showing specific interference of deleted RNA segments with packaging of the corresponding wild-type RNA segment but not with any other genome segment.^{148,149} It will be interesting to define the precise sequences or structures that determine the specific packaging of each segment. Such conserved features must also be compatible with the divergent sequences observed among influenza viruses. For further details about the influenza genome packaging process, please see the reviews by Noda et al.⁴⁸⁸ and Hutchinson et al.³⁰¹

The Budding Process

Initiation of bud formation requires outward curvature of the plasma membrane. The virus bud is then extruded until

the inner core is enveloped. The budding process is completed when the membranes fuse at the base of the bud and the enveloped virus particle is released following fission from the cell membrane (reviewed in (573,587)). It is likely that several of the influenza virus structural proteins contribute to the budding process. HA, NA, and M2, when expressed alone in transfected cells, are all competent to form virus-like particles (VLPs).^{88,352,750} Although M1 obviously participates in the formation of virus particles from infected cells, unlike other viral matrix proteins, it does not appear to possess a late domain sequence that mediates interaction with the cellular ESCRT pathway.^{66,572,715} It has also been demonstrated that in the absence of other viral proteins, M1 does not associate with membranes.⁷⁰⁰ Thus, it appears that there are redundant mechanisms for the initiation of bud formation, and in the context of an infected cell it is presently unclear which of these are dominant. The extent to which the membrane is extruded before pinching off occurs affects the size and shape of the virus particle. Generally, influenza virus particles are either spherical or filamentous, and this characteristic morphology is genetically linked to the M segment^{55,159,564,621} (e-Fig. 40.1). It has been further shown that the determinants for a particular filamentous isolate (A/Udorn/72[H3N2]) map to two residues (R95 and E204) in the M1 protein,⁵⁵ although other residues in M1 as well as in the cytoplasmic tail of M2 are also involved in regulating morphology.^{231,310,564,571} Host factors such as polarization and an intact actin cytoskeleton also play a critical role in determining the morphology of virus particles.^{563,614} The final step of the budding process is membrane scission, which may be facilitated by both viral and cellular factors. The amphipathic helix in the cytoplasmic tail of M2 has been demonstrated to mediate membrane curvature and scission.⁵⁷² Also, the small guanosine triphosphate (GTP)-binding protein, Rab11, has been implicated in this process.⁶⁵

Release

Influenza virus particles have to be actively released after the viral envelope has separated from the cell membrane during the completion of budding. This is because the HA anchors the virus to the cell by binding to sialic acid-containing receptors on the cell surface. The enzymatic activity of the NA protein is required to remove the sialic acid and thereby releases the virus from its host cell. NA activity is also required to remove sialic acid from the carbohydrates present on the viral glycoproteins themselves so that the individual virus particles do not aggregate. The essential function of NA in particle release has been demonstrated through the use of NA inhibitors,^{404,510} ts NA mutant viruses,⁵¹⁶ and NA-deficient viruses.³⁹⁵ In all cases, the absence of NA enzymatic activity was seen to cause viral particles to amass in clumps at the cell surface (Fig. 40.15), resulting in a loss in infectivity that could be restored by addition of exogenous sialidase.

Due to the fact that both HA and NA recognize the same molecule (sialic acid) but have opposing effects (receptor binding vs. receptor destroying), a delicate balance exists between the HA and NA functions.⁶⁹⁷ This is optimized for individual viruses but if disturbed can result in attenuation.⁷⁴⁸

THE NEURAMINIDASE

The NA is the second major glycoprotein of influenza A and B viruses and is a type II integral membrane protein with its

FIGURE 40.15. Aggregate formation of influenza virus particles in the absence of neuraminidase activity. Electron micrograph thin section images showing aggregates of temperature-sensitive neuraminidase (NA) mutant influenza virus grown at nonpermissive temperature (**A**) or grown in the presence of the neuraminidase inhibitor FANA (**B**). For details see (516) and (510).

N-terminus oriented toward the interior of the virus¹⁰⁹ (for review see (204) and for an interesting personal account see (362)). The nine subtypes of the A virus NA fall into two major groups (N1, N4, N5, N8 and N2, N3, N6, N7, N9) based on sequence comparisons¹⁸⁶ (Fig. 40.2). No subtypes have been found for the NAs of B viruses, possibly because these viruses do not have an animal reservoir. The influenza A virus NAs have a highly conserved short cytoplasmic tail and a hydrophobic transmembrane region, which provides the anchor for the stalk and the head domains. The purified head domain of an N2 NA (obtained by pronase treatment of whole virus) was first crystallized by Graeme Laver and its x-ray crystallographic structure was solved by Peter Colman.¹¹² The structure of the N1 NA from the 1918 pandemic virus has also been determined.⁷³⁸ The head of the NA is a homotetramer, each monomer of which is composed of six topologically identical β sheets arranged in a propeller formation. Sugar residues are attached to four of the five potential glycosylation sites in the head (e-Fig. 40.17). The structure of the influenza B virus neuraminidase, similar to that of the A virus, is characterized by the interaction of the sialic acid ligand with nine conserved active site residues.⁷⁸ The enzymatic activity of NA was first recognized by George Hirst, who found that red blood cells treated with virus were refractory to reagglutination by another virus preparation.²⁷⁴ The enzyme was also found to cleave (at position 2 of neuraminic acid) ketosidically bound sugars of alcohols (for review, see (68)), and neuraminidases from different subtypes are described to have different substrate specificities.^{385,543} Transition state inhibitors such as 2-deoxy-2,3-dehydro-N-trifluoroacetylneuraminic acid, which mimic the enzymatic substrate, were shown early on to inhibit influenza virus replication,⁵¹⁵ and compounds with the same mechanism of action were later developed for use as highly effective antivirals in humans (for review, see (214,315,434)). Early work had also elucidated the function of the NA in virus replication. Cells infected by temperature-sensitive mutants with defects in the

NA were shown by electron microscopy to have large aggregates of intact virus particles accumulating near the cell surface (Fig. 40.15). This finding was interpreted to mean that the viral NA must remove the sialic/neuraminic acid receptor from the surface of the cell as well as from the virus particles to prevent recognition by the HA of the virus. The NA thus has a role in releasing the virus from the infected cell and in cleansing the environment (e.g., mucus and cell surfaces in the respiratory tract) of sialic acid receptors to allow for virus spread.^{510,516} In addition, it has been shown that the viral NA may also play a role early in infection, possibly facilitating entry of the virus^{426,493} and/or enhancing late endosome/lysosome trafficking.⁶⁵² As described earlier (see Budding Process), the NA can also mediate virus budding^{352,750} and the cellular restriction factor, tetherin, can influence this step.^{716,750} Another function for at least one subtype NA has also been reported. In the case of an N9 NA, a hemadsorption activity was found to be associated with the purified molecule, and x-ray structure analysis revealed a second independent binding site for sialic acid.⁶⁷⁸ This activity is only associated with avian neuraminidases and appears to be lost upon adaption to humans.⁶⁷³

It is assumed that the function of the influenza B virus NA is similar, if not identical, to that of the A virus NA,^{220,405} and the active sites of influenza A and B virus NAs are conserved, which allows for broad-spectrum activity of NA inhibitors. In influenza C viruses, the receptor-destroying role of the NA is played by the esterase activity of the viral HEF. By removing the acetyl group from 9-O-acetylneuraminic acid, the HEF facilitates the release and spread of virus from infected cells. In addition, it appears that the enzyme is needed for virus entry, suggesting that there is a need for the HEF to be released from cell receptors during the endosomal uptake and fusion/uncoating process.⁶⁸⁸

Like the HA, NA molecules are antigenic and variants are selected in nature. Antibodies directed against the NA are usually not neutralizing, but immunization with NA preparations

has been proposed as an infection-permissive, disease-suppressive vaccine approach against influenza.^{330,654}

Interactions of Influenza Virus with the Host Cell

Cellular Functions Required for Influenza Virus Replication

A virus with a small coding capacity, such as influenza virus, relies on numerous host cell functions in order to complete its replication cycle. In comparison to our understanding of the role of each viral protein in the influenza virus life cycle, we know relatively little about the contribution of host cell proteins. Some well-characterized interactions between viral and host proteins are noted in the sections covering specific viral proteins (e.g., NP and karyopherin α , NEP/NS2 and Crm1, NS1 and CPSF30), but these probably represent only a small fraction of the molecular interactions that occur between influenza virus and its host cell during the viral life cycle. More recent efforts to expand our knowledge of these cellular binding partners have involved a comprehensive yeast two-hybrid analysis of 10 influenza virus proteins (all except PB1-F2), which identified interactions with 87 human proteins.⁵⁹⁶ These interactions exist in a tightly connected network, as 24 of the human proteins interact with two or more viral proteins and there are 51 known interactions occurring between the 87 human proteins. Other studies have examined interacting partners of viral protein complexes rather than individual proteins, and particularly those that retain functionality such as the RNP or trimeric polymerase complexes. Forty-one human proteins were reported to interact with the viral RNP complex of influenza A/WSN/33 (H1N1) virus,⁴²⁷ and 13 interacting proteins were identified in two studies on the WSN polymerase complex.^{323,427} A recent large-scale proteomic analysis of an H5N1 influenza virus polymerase complex has revealed an astonishing 859 human proteins that are associated with either the full polymerase complex or PA-containing subcomponents thereof.⁶⁰ In their analyses, the authors also distinguished between those interactions that are dependent on RNA and those that are not. In summary, 166 PA interacting proteins, 23 that bind to the PB1-PA dimer and 10 that associate with the full polymerase, were identified irrespective of the presence of RNA. Notably, a number of the PA-interacting host proteins are localized to the mitochondria and may be linked to apoptosis. Functional studies are now required to determine if these interacting proteins are required for efficient replication of influenza virus or whether they perhaps play an antiviral role. Using RNAi, 31 proteins known for interacting with the vRNP or polymerase complex were assessed for their role in polymerase activity.⁵¹ Eighteen were shown to facilitate the activities of both H1N1 and H5N1 polymerases, while two antagonized both polymerases, supporting the idea that interacting proteins are likely to play functional roles. Moreover, Bortz et al.⁵¹ showed that an interaction with human DDX17 is specifically associated with promoting activity of the mammalian adapted H5N1 polymerase (PB2 627K), while the chicken homolog is required by the avian H5N1 polymerase (PB2 627E). Thus, knowledge of these interactions provides a molecular basis for host adaptation and contributes to our understanding of differing pathogenicity phenotypes.

Completion of the human genome and the discovery of RNAi have made it possible to query the participation of each

human gene product in functional assays using genome-wide small interfering (siRNA) libraries. Using this powerful tool, genome-wide RNAi screens have been performed on influenza virus-infected cells to identify those genes that are required for efficient virus growth (reviewed in (636,717)). These five studies^{61,254,325,341,596} identified a total of 1,077 unique genes that when targeted by siRNAs lead to decreased influenza virus replication. Each study employed different assay conditions and this likely contributes to the finding that only 85 genes were common to two or more of the screens (34 of these were validated with at least two different siRNAs and with wild-type influenza virus [Fig. 40.16]). However, a greater degree of concordance is seen when one analyzes the results at the level of cellular function rather than gene name.^{600,636,717} Host factors involved in kinase-mediated signaling, pre-mRNA processing, nucleocytoplasmic transport, the COPI complex, and the vacuolar-type H⁺ ATPase (vATPase) complex are all significantly enriched (Fig. 40.16), indicating that these processes are critical for influenza virus replication. Depending on the design of the assay used for the RNAi screen, it is also possible to detect factors that have antiviral activity and thus enhance virus replication when they are depleted. The interferon-inducible transmembrane (IFITM) proteins were identified in this manner and are thought to inhibit entry of influenza virus as well as several other viruses.^{61,292}

Future progress in this area will depend on integrating the data obtained from these global approaches (e.g., proteomics, RNAi, microarray) to build a clearer picture of the cellular networks that govern efficient influenza virus growth. Such information may address questions concerning species specificity and also provide new avenues to explore for drug discovery (see section on Inhibition of Cellular Factors).

The Actions of the NS1 Protein

When a virus infects a cell, it has to contend with the rapid onset of the host innate immune response, whose mission it is to establish an antiviral state within the cell and prevent virus replication. A critical component of this response is type I interferon (IFN- α/β), which is secreted from virus-infected cells. A characteristic feature of all orthomyxoviruses is their sensitivity to the inhibitory effect of IFN-inducible Mx GTPases.²⁵¹ In fact, IFN was first described as a factor induced by heat-inactivated influenza virus,³⁰⁵ although interestingly, live influenza virus was found to inhibit the induction of IFN by inactivated virus.³⁹⁴ The reason for this observation did not become clear until almost 40 years later when, with the benefit of reverse genetics technology, it was possible to engineer an influenza A virus that lacked the *NS1* gene (delNS1).²¹³ This virus displayed unusual growth properties as it was severely attenuated in IFN-competent systems but grew well in IFN-deficient systems such as Vero cells and 6-day-old embryonated eggs and was lethal in STAT1^{-/-} mice^{213,657} (e-Fig. 40.18). Thus, in the absence of an IFN response, NS1 appears to be dispensable, whereas in the context of an immune-competent host, it is essential. Microarray analysis has demonstrated that infection with delNS1 virus leads to enhanced expression of IFN and IFN-regulated genes compared to wild-type influenza virus infection,²¹⁸ and NS1 is therefore termed an *IFN antagonist* because it acts to suppress the virus-induced host IFN response (reviewed in (245,727)). These findings have given rise to a new concept for the design of live-attenuated vaccines based on mutations in the NS1 gene⁶⁵⁷ (reviewed in

FIGURE 40.16. Graphical representation of the 34 best validated host factors identified in the influenza virus RNA interference (RNAi) screens. Analysis of the validated hits from the RNAi screens by Brass et al,⁶¹ Karlas et al,³²⁵ and König et al³⁴¹ resulted in a list of 34 genes that were identified in at least two screens. These 34 host cell factors are shown with regards to their localization within the cell and in context of the viral replication cycle. The four different groups of host proteins with known function in the viral life cycle are depicted in colored symbols: (1) components of the viral adenosine triphosphatase (vATPase) complex, (2) COPI proteins, (3) nucleocytoplasmic transport factors, and (4) members of the splicing machinery. The host factors with as yet unknown function are illustrated with gray symbols. See (636) for details. (Reprinted from Stertz S, Shaw ML. Uncovering the global host cell requirements for influenza virus replication via RNAi screening. *Microbes Infect* 2011;13[5]:516–525; with permission from Elsevier.)

(511,512,557)). Studies on viruses expressing truncated forms of NS1 have shown that the level of attenuation is determined by the amount of IFN induced by the virus (i.e., highly attenuated viruses induce larger quantities of IFN),^{27,174,549,627,657} and immunization with these mutant viruses produced protective immunity in mice, chickens, swine, horses, and macaques (reviewed in (557)).

STRUCTURAL FEATURES OF THE NS1 PROTEIN

NS1 is a nuclear, dimeric protein that is highly expressed in infected cells and has a dsRNA-binding domain, an effector domain, and a disordered tail (reviewed in (250)). The RNA-

binding domain lies within the N-terminal 73 amino acids (548), for which both NMR and crystal structures have been obtained.^{96,97,397,749} These data indicate that the NS1 RNA-binding domain forms a symmetric homodimer with a six-helical fold and that conserved tracks consisting of basic and hydrophilic residues on each monomer mediate interactions with dsRNA. Mutational analysis has further demonstrated that dimer formation is crucial for RNA binding as are residues R38, R35, and R46.^{96,710} Residue K41 strongly enhances the binding affinity⁷¹⁰ and residues S42 and T49 also participate in dsRNA binding.⁹⁶ It is suggested that the basic residues make contact with the phosphate backbone of the RNA via electrostatic

interactions,^{98,710,749} which is consistent with the observed lack of sequence specificity.^{259,548} Structural data indicate that the NS1 dimer spans the major groove of canonical A-form dsRNA in a length-independent mode.⁹⁶ Structures of the influenza B virus NS1 RNA-binding domain indicate a similar binding mode.⁷⁴⁹

The remaining portion of NS1 has been termed the effector domain and includes binding sites for several host factors (as reviewed in (250)) (e-Fig. 40.19). Crystallographic structures of the NS1 effector domain have been determined for several influenza A virus strains. While the monomer conformation is very similar, different dimer interfaces have been determined, specifically, one that is mediated by a helix–helix interaction^{12,246,328,733} and another mediated by a strand–strand interaction.^{49,329} The helix–helix interaction is dependent on residue W187 in each monomer,^{246,734} and it has been proposed that the monomer interface can twist and therefore the dimer can exist in both open and closed conformations.³²⁸ Finally, one structure of a full-length NS1 protein has been reported.⁵⁰ Strikingly, instead of individual dimers, NS1 is shown to form a chain with alternating interactions occurring via the dsRNA-binding and effector domains. Moreover, three of these chains are shown to interact with one another to form a tubular structure that can accommodate dsRNA in its center. This chain-

like structure opens up questions regarding how interactions between NS1 and its cellular partners can be accommodated, but models for how this may occur in the context of an individual NS1 dimer have been proposed.³²⁸

INHIBITION OF INTERFERON SYNTHESIS

Wild-type (WT) influenza virus infection induces far less IFN than does delNS1 virus, and this difference lies at the level of mRNA molecules.^{218,656,712} This implies that NS1 either acts to prevent the synthesis of IFN mRNA or destabilizes IFN mRNA. The transcriptional activation of IFN- β in response to virus infection is regulated by transcription factors including interferon regulatory factor-3 (IRF-3), nuclear factor- κ B (NF- κ B), and activator protein-1 (AP-1). Each one of these transcription factors has been shown to be activated in delNS1 virus-infected cells but not in WT virus-infected cells,^{403,656,712} which corresponds with the differential induction of IFN- β by these viruses. Moreover, expression of NS1 alone inhibits the activation of the IFN- β promoter in response to infection with a heterologous virus or even delNS1 virus.^{403,712} Substantial progress has been made to understand the precise mechanism by which NS1 suppresses IFN synthesis (reviewed in (245,250)) (Fig. 40.17). First, dsRNA binding is important as

FIGURE 40.17. Schematic diagram of the multiple functions of NS1 within infected cells. **A:** Pretranscriptional limitation of interferon- β (IFN- β) induction. **B:** Inhibition of the antiviral properties of protein kinase R (PKR) and 2'-5'-oligoadenylate synthetase (OAS)/RNase L. **C:** Posttranscriptional block to processing and nuclear export of all cellular messenger RNAs (mRNAs). **D:** Enhancement of viral mRNA translation. **E:** Activation of phosphatidylinositol 3 kinase (PI3K). Some other interactions that have been characterized are detailed in the **lower box**. See (250) for details. (Adapted from Hale BG, Randall RE, Ortin J, et al. The multifunctional NS1 protein of influenza A viruses. *J Gen Virol* 2008;89[Pt 10]:2359–2376; courtesy of Ben Hale.)

expression of the RNA-binding domain alone is sufficient to block virus induction of IFN.⁷¹² However, a virus expressing only the first 73 residues is still attenuated in mice (with a phenotype intermediate to that of delNS1 and WT virus), pointing to a role for the effector domain *in vivo*.^{174,657,711} Alanine substitution of the residues involved in RNA binding (R38 and K41) was found to significantly reduce the ability of NS1 to inhibit IRF-3 and NF- κ B activation^{656,712} and, hence, IFN- β synthesis.¹⁴³ In the context of a virus, these mutations resulted in increased IFN- β production and, therefore, an attenuated phenotype in mice.¹⁴³ Second, NS1 is found in complex with the cytoplasmic sensor RIG-I and acts to prevent RIG-I signaling and IFN- β production.^{238,444,501,530} This interaction appears to depend on the same residues implicated in dsRNA binding, indicating that it is potentially mediated by RNA.⁵³⁰ Third, NS1 interacts with TRIM25 via residues E96 and E97.¹⁹⁹ TRIM25 is responsible for ubiquitinating and activating RIG-I and the presence of NS1 blocks this activity.

INHIBITION OF PROTEIN KINASE R AND THE RNASE L PATHWAY

Protein kinase R (PKR) is activated in the presence of dsRNA (i.e., during virus infection) and is responsible for the phosphorylation of the eIF2 α subunit, which causes protein translation to cease and thus prevents further viral replication. Not surprisingly, many viruses have devised ways of blocking the activation of PKR, and influenza virus does so via two different mechanisms. PKR expression is induced by IFN and therefore the NS1-induced block in IFN synthesis will reduce the levels of PKR in infected cells. In addition, NS1 has been shown to inhibit PKR activation by sequestering its activator, dsRNA,^{261,401} and NS1 has also been observed to form a complex with PKR,⁶⁵⁹ which inhibits its activation in response to both dsRNA and the cellular PACT protein.³⁷⁸ The role of NS1 in PKR inhibition has been demonstrated *in vivo*, as seen by restoration of delNS1 virus replication in PKR^{-/-} mice with an accompanying increase in pathogenicity.³⁷ Via a similar mechanism (i.e., sequestration of dsRNA), NS1 can prevent activation of the 2'-5'-oligoadenylate synthetase (OAS)/RNase L pathway.⁴⁴⁵

INHIBITION OF HOST mRNA PROCESSING

Influenza virus-infected cells harbor pre-mRNAs in their nuclei that do not undergo efficient 3'-end processing and therefore cannot be exported.^{94,607} This is thought to be an NS1-mediated effect that occurs via interaction of the NS1 effector domain with two components of the 3'-end processing machinery: the 30-kD subunit of the cleavage and polyadenylation specificity factor (CPSF)^{131,338,473} and the poly(A)-binding protein II (PABII)⁹⁴ (reviewed in (245,250,346)). The NS1 interaction effectively inhibits these processing factors and results in pre-mRNAs that either remain uncleaved^{473,607} or only acquire short poly(A) tails.⁹⁴ NS1 also inhibits splicing of pre-mRNAs, which also results in their retention in the nucleus,^{185,400} and evidence for the requirement of CPSF in splicing suggests that both of these mRNA-processing defects in influenza virus-infected cells may be related to the inhibition of CPSF.³⁸⁶ NS1 also interferes with mRNA export via complex formation with several components of the nuclear export machinery.⁵⁸⁴ As the induction of the host antiviral response relies so heavily on transcriptional up-regulation of genes, this global posttranscriptional inhibition may aid in aborting or at least delaying the onset of this response. This is

reflected in data from a CPSF-binding mutant virus, which is attenuated in tissue culture and which causes an earlier induction of antiviral gene products compared to WT virus.⁴⁸⁶ It should be noted, however, that the delNS1 virus shows shutoff of host protein synthesis at levels similar to that of wild-type virus.⁵⁸¹ This suggests that other (or additional) factors may be responsible for inhibition of general gene expression.

ADDITIONAL NS1 INTERACTIONS WITH HOST CELL FACTORS

The influenza A virus NS1 protein binds directly to the p85 β regulatory subunit of PI3K via its C-terminal effector domain, and NS1 expression is sufficient to activate PI3K signaling.^{153,248,610} Specifically, residues Y89, M93, P164, P167, L141, and E142 in the NS1 protein, which are located in predicted src homology 2 (SH2)- and SH3-binding motifs, have been implicated in the interaction with p85 β .^{248,384,609,610} The NS1-binding site on p85 β is located in an inter-SH2 domain,²⁴⁷ and a co-crystal of the NS1 effector domain in complex with this region of p85 β shows that residues Y89 and P167 of NS1 are at the binding interface.²⁴⁹ Furthermore, a model of a heterotrimeric complex consisting of NS1-p85 β -p110 predicts that the presence of NS1 would disrupt the inhibitory contact between p85 β and p110.²⁴⁹ This explains the PI3K-activating properties of NS1, which theoretically serve to delay apoptosis at late stages of infection.¹⁵¹ However, recombinant viruses expressing NS1 proteins that fail to activate PI3K were not seen to induce any more apoptosis than wild-type virus, so the biological significance of NS1-mediated PI3K activation remains unclear.³¹⁴ It also should be noted that a pro-apoptotic activity of NS1 has been reported.⁵⁹²

NS1 has also been reported to interact with several other host factors (e-Fig. 40.19), including the eukaryotic translation initiation factor 4GI, poly (A)-binding protein I, stauferin, NS1-I and NS1-BP, nucleolin, hnRNP-F, E1B-AP5, Herc5, PAB-II, importin α , CrkL, scribble, Dlg1, PDLim2, p15, NXF1, Rae1, PACT, and Ubc9.^{11,76,94,168,225,266,289,368,396,438,463,584,588,660,728,729,751,763} It has been shown that disruption of the stauferin-1/NS1 interaction inhibits influenza virus replication, indicating that this virus-host interaction is required for optimal virus growth.³⁶⁹

ANTI-INTERFERON PROTEINS OF INFLUENZA B AND C VIRUSES, THOGOTO VIRUS, AND ISAVIRUS

Like its A virus counterpart, the NS1 protein of influenza B virus (B/NS1) exists as a dimer and has RNA-binding activity in its N-terminal domain (residues 1 to 93).^{144,709,753} A virus lacking B/NS1 has also been demonstrated to induce larger amounts of IFN than WT virus,¹³² and the B/NS1 protein can complement the growth of influenza A delNS1 virus,¹⁴⁴ indicating that A/NS1 and B/NS1 are functional equivalents. Therefore, as described for influenza A virus, recombinant influenza B viruses either lacking NS1 or expressing truncated NS1 proteins have been proposed as vaccine candidates.^{244,731} Expression of B/NS1 has been shown to inhibit virus activation of the IFN- β promoter,^{132,144} but interestingly, both N- and C-terminal domains of the protein encode this inhibitory activity and hence RNA binding was found not to be essential for inhibition of IFN- β synthesis.¹⁴⁴ However, in the context of the N-terminal domain alone, RNA binding was required. Similarly, both portions of B/NS1 were shown to independently inhibit virus activation of the transcription factor, IRF-3.¹⁴⁴ B/NS1 is also an inhibitor

of PKR, but unlike A/NS1 it does not interfere with mRNA processing.⁷⁰⁹ B/NS1 does possess the unique ability to bind to *ISG15* (an IFN-inducible gene) and prevent its conjugation to target proteins,⁷⁵⁴ which it does through its N-terminal domain independently of RNA binding.⁷⁵³ Structural analysis shows that a dimer of the B/NS1 N-terminal domain interacts with two ISG15 molecules, with each ISG15 binding distinct regions of each NS1 monomer.²³³ ISG15 conjugation or ISGylation has been shown to regulate the IFN signaling pathway and to be critical for host antiviral defense.^{413,558,762} Interestingly, B/NS1 inhibits ISGylation in a species-specific manner, binding only to human and nonhuman primate ISG15.^{628,684} This likely contributes to the fact that influenza B infections are restricted to humans. The influenza B virus NS1 protein may also have a role in virus replication as the virus lacking B/NS1 grows to lower titers, even in IFN-deficient cells.¹³² It has also been shown that B/NS1 associates with nuclear speckles and that this is linked to residues in its N-terminal region.⁵⁸⁸

The influenza C virus NS1 protein (C/NS1) has been shown to inhibit RIG-I-mediated activation of the IFN- β promoter through a region located in its C-terminus.⁵⁰⁷ C/NS1 has also been shown to up-regulate splicing of viral mRNAs.⁴⁵⁸

Unlike the influenza viruses, Thogoto virus does not have an NS segment and instead its anti-IFN activity is encoded by the M segment.²⁴² The M segment produces the M protein from a spliced transcript and the ML protein from an unspliced transcript, of which the latter has been shown to be an IFN antagonist protein.^{242,339} As seen with the delNS1 influenza virus, a recombinant Thogoto virus lacking the ML protein was shown to induce far greater levels of IFN in infected cells than WT virus²⁴² and was remarkably attenuated in mice expressing functional Mx1 (an IFN-inducible protein that protects against orthomyxovirus infection).⁵²⁹ ML has also been demonstrated to inhibit virus-induced activation of IRF-3 but in a manner distinct from that of NS1.³¹⁶ Another striking difference between ML and NS1 is that ML is a structural protein.²⁴¹ Because expression of ML is controlled by the same promoter as that of the M protein (which is expressed late in infection), this strategy ensures that ML is present at the initial stages of virus infection when it can most effectively exert its effect on the host immune response.

The isavirus IFN antagonist proteins are expressed from the unspliced transcript of RNA segment 7 and the larger open reading frame (ORF) of RNA segment 8.^{122,211}

The Actions of the PB1-F2 Protein

Influenza A viruses can express an 11th protein, PB1-F2, which is encoded by the +1 alternate ORF in the *PB1* gene.⁹³ PB1-F2 is 87 to 90 aa long, depending on the virus strain, and is expressed by most human H3N2 viruses, while a large number of human H1N1 isolates have a premature stop codon in the PB1-F2 ORF. Of note, the pandemics that occurred in 1918, 1957, and 1968 were all caused by influenza viruses that express full-length PB1-F2. The protein has been shown to contribute to influenza virus pathogenicity through several mechanisms. Initially, a pro-apoptotic function was described for PB1-F2. It was found to localize to mitochondria and disturb the mitochondrial membrane potential, leading to the efflux of cytochrome c into the cytoplasm.^{93,221} The induction of apoptosis by PB1-F2 is thought to occur specifically in immune cells in a strain-dependent manner and thus contribute to immune

evasion by influenza viruses.^{93,428,756} It was demonstrated that PB1-F2 triggers an apoptotic response by interacting with the mitochondrial adenine nucleotide translocase 3 (ANT3) and voltage-dependent anion channel 1 (VDAC1) proteins⁷⁵⁵ and/or form pores via self-oligomerization^{67,84,269} (Fig. 40.18).

In addition to its pro-apoptotic activity, PB1-F2 was reported to have pro-inflammatory properties. Specifically, it was observed that PB1-F2-expressing viruses increase the levels of several cytokines and chemokines, enhance cell infiltration, and exacerbate lung injury in infected mice.^{117,118,428,429} Notably, it was found that a serine (S) at position 66 in the PB1-F2 protein dramatically increases immunopathology and mortality caused by the 1918 pandemic strain and by highly pathogenic H5N1 viruses.¹¹⁸ Transcriptional profiling of mice infected with a PB1-F2 N66S-expressing virus revealed an early suppression of interferon-stimulated genes (ISGs)¹¹⁷ and *in vitro* studies demonstrated an anti-interferon activity of PB1-F2 at the level of the MAVS adaptor protein⁶⁷⁷ (Fig. 40.18). Interestingly, PB1-F2 N66S, which is associated with increased pathogenicity, inhibited the induction of IFN more efficiently than a wild-type PB1-F2 protein.⁶⁷⁷ It is hypothesized that there may be a possible link between the pro-apoptotic and anti-interferon functions of PB1-F2 through the MAVS protein.⁶⁷⁶

REVERSE GENETICS

Because the *Orthomyxoviridae* are negative-strand RNA viruses, introduction of the genomic RNAs into cells does not result in the formation of infectious virus (as it does in the case of positive-strand RNA viruses). Initial experiments eventually leading to the genetic engineering of influenza viruses involved the reconstitution of functional RNP complexes *in vitro*^{282,522} and transfection of functional RNPs into cells. In these experiments, cDNA-derived RNA for a specific segment was mixed with purified virion NP and polymerase proteins and transfected into cells before or after infection with a helper influenza virus in order to provide the remaining vRNP segments.⁴⁰⁹ Rescue of infectious virus containing the cDNA-derived RNA required selection of the novel virus against the helper virus.¹⁶⁵ Alternatively, cells were transfected with a plasmid construct containing the gene of interest flanked by an RNA polymerase I promoter and terminator sequences. Cellular RNA polymerase I normally transcribes rRNA (which lacks a 5' cap and 3' poly[A] tail), and therefore the RNA synthesized from the plasmid construct is an exact replica of the vRNA. The viral polymerase proteins were supplied by transfection with polymerase II-driven expression plasmids, and the remaining genomic segments were provided by infection with a helper influenza virus.^{480,535} A disadvantage of these early systems was the need for helper virus, which must be selected against in order to isolate the rescued virus.

In 1999, a decade after the initial influenza reverse genetics system had been described, Fodor et al.¹⁷⁸ and Neumann et al.⁴⁷⁹ reported the generation of influenza viruses entirely from cloned cDNAs. In the system reported by Fodor et al, cDNA from each of the eight genome segments was cloned in negative orientation between a truncated human RNA polymerase I promoter and the hepatitis delta virus ribozyme.¹⁷⁸ Transfection of the eight vRNA-encoding plasmids into Vero cells along with four polymerase II-driven plasmids expressing NP and the polymerase complex (PB1, PB2, PA) resulted in

FIGURE 40.18. The pro-apoptotic and anti-interferon activities of the influenza A virus protein PB1-F2. The protein promotes apoptosis by interacting with the mitochondrial VDAC1 and ANT3 proteins and interferes with the induction of interferon at the level of the MAVS adaptor protein. Cyto c: cytochrome c. (Courtesy of Zsuzsanna T. Varga.)

recovery of infectious virus (Fig. 40.19). As helper virus is not required for the generation of recombinant virus, the cumbersome selection process was unnecessary. Improvements to this system now include the transfection of co-cultured 293T cells (necessary due to the human RNA polymerase I promoter) and

Madin Darby Canine Kidney (MDCK) cells, which support high levels of virus replication (for review, see (478)).

Further improvements to these systems were reported in which only eight plasmids were required.^{278,279} The plasmids contained cDNAs of genomic segments cloned in negative

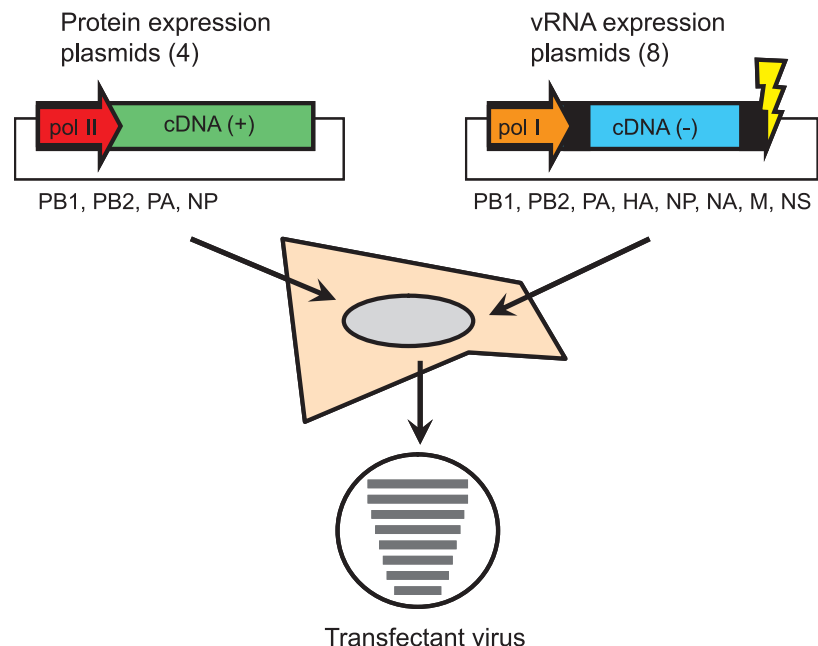

FIGURE 40.19. Schematic representation of the plasmid-based rescue system for influenza A virus. The negative-sense complementary DNA (cDNA) for each viral segment is cloned between a polymerase I promoter and the hepatitis delta virus ribozyme or polymerase I terminator. These eight plasmids are transfected into mammalian cells along with four expression plasmids for the polymerase proteins and nucleoprotein (NP). The resulting transfectant virus is then passaged on fresh cells. For details see (178). (Courtesy of Adolfo García-Sastre.)

orientation with a human RNA polymerase I promoter at the 5' end and the mouse RNA polymerase I terminator at the 3' end. The cellular RNA polymerase I was responsible for the copying of the cDNA into vRNA. Downstream of the RNA polymerase I terminator was a CMV immediate-early promoter. A polyadenylation sequence was inserted at the other end, giving rise to a polymerase II-driven mRNA transcript from the opposite DNA strand. Expressed viral proteins and vRNAs then assembled in the transfected cells and resulted in the formation of infectious virus derived entirely from only eight plasmids. A single plasmid containing the cDNAs of all eight RNAs resulted in the generation of infectious virus when transfected into human cells.⁴⁷⁶ Most likely, transcription of mRNA-like molecules occurred from this plasmid, which then gave rise to the formation of the complementing viral polymerase proteins. These proteins, together with the full-length vRNA segments (also transcribed from the plasmid), allowed rescue of fully infectious virus. Another one-plasmid system was developed for the rescue of influenza A viruses in chicken cells.⁷⁶¹ Other modifications of the rescue system involve the use of uncloned PCR-amplified products, which obviates possible problems in cloning toxic sequences,^{772,773} and the use of adenovirus as a vector to deliver the required plasmid constructs.⁵⁰⁴ Finally, de Wit et al.¹³⁴ designed a rescue system built on transcription by the T7 polymerase, which allows the rescue of influenza viruses in practically all cells independent of the species origin.

Influenza viruses expressing foreign genes have also been generated, demonstrating the use of influenza virus as a vector to deliver foreign antigens to the immune system. Numerous approaches have been successful for the expression of foreign antigens by influenza viruses. These include (a) replacement of the antigenic domains of either the influenza HA or NA glycoproteins with epitopes from foreign proteins.^{379,380} (b) Modification of existing viral genomic segments to express influenza viral proteins fused to foreign proteins. These polyproteins can subsequently be cleaved into two proteins. Also reported was the rescue of an influenza virus that expresses an uncleaved chimeric HA with a 140-amino acid insertion of the receptor-binding domain of the *Bacillus anthracis* protective antigen (PA).³⁸⁹ (c) Replacement of ectodomains of surface glycoproteins with those of foreign glycoproteins.¹⁷⁵ (d) Preparation of viruses with foreign antigens encoded by a ninth RNA segment (for review, see (212,478)).

Advantages of influenza viruses over other viruses for the expression of foreign proteins include the fact that influenza virus is extremely safe as a nonintegrating, nononcogenic virus. Infection with influenza viruses also elicits a strong and long-lasting immune response, and thus recombinant influenza viruses may be useful vaccine vectors in the future. The limitations related to the use of influenza viruses for expression of foreign antigens include the limited (but not yet well-defined) capacity of influenza viruses to express foreign sequences and the requirement of packaging signals on both the 5' and 3' ends of the vRNA, which may interfere with the expression of foreign genes.

The advances of reverse genetics techniques have been of great benefit to the study of structure/function of different influenza virus genes and their proteins. In many cases, the definitive role of a gene or of a domain (or even of a single amino acid) can only be explored by introducing appropriate mutations into the genome of the virus and then analyzing the phenotype of the rescued virus. As discussed, rescue systems have been described

for influenza A viruses (for review see (212,367,422)) and B viruses^{277,312} (for review see (313)). Also, rescue systems have now been developed for influenza C viruses^{125,460,506} (for review see (459)). Influenza viruses have been generated that express chimeric (type A/B) HAs and NAs. For example, such viruses may express, in a type A genetic background, the extracellular portion (ectodomain) of an influenza B HA and/or NA.^{175,285,287} These findings show that the HA and NA of an influenza A virus can be functionally replaced with the corresponding protein from an influenza B virus. In turn, viruses have been made in the influenza B virus background expressing proteins derived from influenza A viruses.²⁴³ By taking advantage of the knowledge about packaging sequences, influenza A viruses have been made to contain nine segments expressing an H1 and an H3 HA²⁰⁷ or only seven segments.²⁰⁶ In the latter virus the HA and the NA have been replaced by the HEF protein of an influenza C virus. Whole organ imaging and analysis of infected cells is now facilitated by chimeric influenza viruses that express a green fluorescent protein (GFP) molecule for visualization of influenza virus-infected cells.⁴¹⁴ Reverse genetics has also been successfully used to rescue an influenza virus expressing all eight genes of the "extinct" 1918 pandemic virus, which has allowed its extraordinary virulence to be studied.^{517,671}

Reverse genetics has also helped in designing improved influenza virus vaccines. The live attenuated pH1N1 2009 vaccine was made from a plasmid-generated strain, into which HA gene mutations were introduced to give high yields without changing the antigenicity of the strain.⁹⁵ Also, killed and live pandemic H5N1 virus vaccines were prepared using reverse genetics, allowing the removal of the basic peptide from the HA cleavage site, in order to make the strains used for manufacturing less virulent (for review (286)).

Thogoto virus, which has six negative-strand RNA segments, has also been rescued by a reverse genetics system.^{337,695} The viral RNAs were transcribed from the plasmids under the control of a polymerase I promoter and the structural proteins were expressed from six plasmids driven by a T7 polymerase promoter in the presence of a T7 vaccinia recombinant.

INHIBITORS OF INFLUENZA VIRUSES

Because influenza viruses remain a constant health threat, major efforts have been directed at discovering effective antivirals over the past several decades. Presently there are four Food and Drug Administration (FDA)-approved drugs available for use in humans: amantadine, rimantadine, oseltamivir, and zanamivir (Fig. 40.20). Past and current approaches to antiviral therapy are briefly discussed here (according to the step in virus replication targeted by each drug). Extensive reviews cover the vast literature on this subject.^{28,36,46,110,216,264,315,406,408,562}

Inhibition of Attachment and Uncoating

While vaccination, in essence, targets the HA so that specific antibodies are generated that block attachment of the virus to the receptor, drugs that interfere with the HA-sialic acid interaction have not been successfully developed. This is perhaps surprising because the x-ray crystallographic structures of the HA and of HA-ligand complexes have now been known for more than two decades. In principle, such an approach could work,^{101,223} but this strategy, using sialic acid analogs (or polymers bearing sialic acids), has not led to an FDA-approved

FIGURE 40.20. Anti-influenza virus compounds. The chemical structures of (A) zanamivir (Relenza), (B) oseltamivir (Tamiflu), (C) amantadine (Symmetrel), and (D) rimantadine (Flumadine) are shown.

drug. Whether removal of receptor molecules from the respiratory tract by administration of exogenous sialidase/neuraminidase is a viable antiviral approach remains to be seen. A sialidase fusion protein, DAS181, has been shown to be an effective antiviral strategy in tissue culture and animal models.^{35,361} However, it seems doubtful that receptors could be (safely) denuded for extended periods of time in order to prevent infection by influenza viruses.

Quinone derivatives that prevent the first stage of the conformational change of the HA and thus inhibit infection were discovered in 1993,⁴⁵ and other compounds with a similar mechanism showed inhibition for some strains but not for others.^{106,630} Compounds have also been identified that appear to push the HA into an inactive state²⁷⁶ or that associate with the N-terminal heptad-repeat trimer, thus interfering with the *trimer of hairpins* (helix bundle) formation.¹⁰⁵ This latter approach would be similar to that successfully applied for human immunodeficiency virus (HIV) using the fusion inhibitor T-20.³³¹ In addition, several other approaches aimed at preventing virus attachment have been reported.^{201,237,374,579,620,629} Nitazoxanide (a thiazolide) is reported to prevent terminal glycosylation of HA and thereby impair HA maturation and trafficking to the cell surface.⁵⁷⁰ So far, none of the influenza virus HA inhibitors has advanced beyond the experimental stage.

Another approach concerns the inhibition of the post-translational cleavage of the HA, which results in a molecule unable to undergo the conformational change required for fusion/uncoating. Several exogenous protease inhibitors have been investigated,^{34,52,371,770,771} of which aprotinin has been

found to be effective in humans.⁷⁶⁸ Drugs belonging to this general class have been successful against HIV but have not been further developed for widespread therapeutic or prophylactic use against influenza in humans.

Amantadine, which has been known for many decades to inhibit most influenza A viruses, has been found to target the M2 ion channel (for details see M2 Protein). During uptake, virus enters endosomes where the acid pH activates the ion channel, resulting in the transport of protons into the viral interior. This process, which is required for the dissociation of the RNP complex from the M1 protein and subsequent release of the RNP into the cytoplasm, is blocked by amantadine and its derivatives (including rimantadine),⁷²² (for review see (533)). In addition, amantadine can affect the pH regulation of vesicles involved in the transport of viral glycoproteins to the cell surface during assembly.⁶³⁴ Thus, there are two possible steps at which amantadine can exert an antiviral effect: uncoating and HA stability (in some strains) during transport in vesicles. Unfortunately, resistance to amantadine and to its 10-fold more active derivative, rimantadine, develops with increased use in humans and animals (for review see 452). In fact, according to Centers for Disease Control and Prevention (CDC) guidelines, adamantanes are not recommended for clinical use as of 2010/2011.

Inhibitors of the Viral Replication Complex

The viral RNA-dependent RNA polymerase is a good antiviral target as it possesses unique features not found in the cell. Tomassini et al.^{665,666} reported that 2,4-dioxobutanoic acid and

2,6-diketopiperazine derivatives selectively inhibit the endonuclease activity (PA) of the influenza virus polymerase. Recent knowledge of the PA structure will encourage investigation of endonuclease inhibitors.¹³⁰

Ribavirin (which is approved for treatment of hepatitis C) and several other nucleotide analogs are known to inhibit influenza in humans, but toxicity remains a problem (for review see (376,406)). For RNA viruses, most of the antiviral effects of ribavirin are likely due to incorporation as a purine analog, resulting in lethal mutations. Similarly, T-705 (favipiravir) inhibits influenza virus RNA polymerase activity by acting as a purine analog and has been shown to be effective against several RNA viruses.^{195,196,334} Also, capped and uncapped RNA fragments interfering with cap binding, capped-RNA primed transcription, or panhandle formation have been reported (for review see (406)), but these compounds would have pharmacologic limitations because of difficulties in getting charged molecules into cells. Recent high-throughput screens of small molecules have uncovered novel inhibitors of influenza virus replication that target the NP and PB1 proteins.^{324,645}

Antisense Oligonucleotides and siRNAs

Synthetic oligodeoxynucleotides in the phosphorothioate series corresponding to sequences in the *PB1* gene of influenza A and C viruses were found to inhibit virus replication,³⁷⁵ possibly mediated through an antisense RNA mechanism (for review see (408)). More recently, siRNA inhibition has become a promising route to interfere with influenza virus replication in tissue culture and in animals (for review see (23,36,216,594)). RNAi is a process by which small molecules of double-stranded RNA direct the sequence-specific degradation of mRNA molecules. Theoretically, viral mRNA as well as cRNA and vRNA could be targets for an siRNA approach, and several siRNA molecules directed against specific influenza virus genes have been shown to successfully inhibit influenza virus replication in tissue culture and mice.^{217,297,382,649,667} Challenges of this approach remain: First, the effective delivery of these molecules defies standard approaches. Second, contradictory results have been reported regarding the induction of interferons and cytokines by siRNAs, which may represent an obstacle to their use as specific and nontoxic inhibitors.^{411,561,619}

NS1 Inhibitors

The NS1 protein is being considered as a possible antiviral target due to its role as a pathogenicity factor. Loss of NS1 activity should restore normal immune function to influenza virus-infected cells and promote viral clearance. For this reason small-molecule inhibitors that are able to reverse NS1-mediated inhibition of the innate immune response are being sought. One such molecule has been described that is dependent on an intact IFN response and, specifically, RNase L.^{29,698} Some screens have focused specifically on compounds that may act by disrupting the interaction of NS1 with RNA,^{3,415} while others have examined NS1-mediated inhibition of host gene expression.⁴²³

Neuraminidase Inhibitors

The study of temperature-sensitive mutants with defects in the NA of influenza viruses has shown that the function of this enzyme is to release the newly formed virus from the cell surface.⁵¹⁶ Also, it was shown that neuraminic acid analogs inhibit influenza virus replication in tissue culture and that aggregates

of virus are formed at the cell surface in the presence of these drugs^{510,515} (Fig. 40.15). By relying on the three-dimensional x-ray structure, von Itzstein et al.⁶⁸⁹ designed a derivative of neuraminic acid that had a guanidino group at C atom 4 instead of the OH group of the previously studied neuraminidase inhibitor, DANA (e-Fig. 40.20).⁴³⁶ This compound, zanamivir (Fig. 40.20), is not orally bioavailable and is FDA approved for administration by inhalation or by nasal spray. Most recently intravenous administration has been investigated.⁵⁵² In numerous studies, this compound has been shown to be a potent anti-influenza drug, both prophylactically and therapeutically (for review, see (108,214,315,434)). Peramivir is another neuraminidase inhibitor that can be administered intravenously.³⁴⁰ It received emergency approval in the United States during the 2009 H1N1 pandemic and is already approved in several Asian countries. A long-acting neuraminidase inhibitor (laninamivir), which requires a single administration for the entire course of treatment, was recently developed.⁷³⁹ A search for compounds that are orally active led to oseltamivir.³⁸¹ Its prodrug is an ethyl ester of a compound that has the three OH groups of C atoms 7, 8, and 9 of sialic acid replaced by a hydrophobic side chain, thus making the drug pass through the gut into the bloodstream (Fig. 40.20). This systemically active compound has been shown to be highly effective against both influenza A and B viruses, including strains containing the NA gene of the 1918 pandemic virus,⁶⁷² (for review see (306,315,434)). Although oseltamivir-resistant variants had been described with escape mutations in the HA as well as the NA,^{20,111,234,311,333} it was still unexpected that such widespread resistance would be seen among the seasonal H1N1 viruses by the 2009 season.^{298,500} Prior to 2007, the presence of the NA H274Y mutation was associated with a cost to viral fitness.^{270,308} By 2008/2009, this mutation had a fitness advantage even in the absence of oseltamivir and these resistant viruses were shown to be highly transmissible in a guinea pig model.⁵⁸ It has been proposed that compensating mutations in the NA resulted in a more stable molecule with enhanced expression at the cell surface than was observed for a mutant with only the H274Y mutation.⁴⁴ Interestingly, for the H3N2 viruses, oseltamivir resistance is associated with a loss of fitness and is detrimental to transmissibility of these viruses.^{57,747} However, resistant H3N2 viruses have been isolated particularly from immunocompromised patients undergoing therapy.^{442,494} Similarly, oseltamivir-resistant isolates of the 2009 pandemic virus have been observed in these patients but not in the community.^{230,441} Based on experiments in animal models, it is predicted that an H275Y change in the NA of the 2009 pandemic virus would not be associated with any substantial loss in fitness or transmissibility.^{146,440,593} With this virus already being resistant to the adamantanes, acquisition of oseltamivir resistance would make it a multidrug-resistant virus and a significant threat. Fortunately, mutations associated with oseltamivir resistance do not generally confer zanamivir resistance, and there are rare reports of zanamivir resistance in patients.²³⁵ Structures of oseltamivir-resistant NAs that remain sensitive to zanamivir show that this is due to an altered hydrophobic pocket in the active site that affects oseltamivir but not zanamivir binding.¹⁰⁷

Inhibition of Cellular Factors

The identification of host factors that are required for optimal influenza virus replication (see section Cellular Functions Required for Influenza Virus Replication) provides additional

targets that can be explored for potential antiviral development (reviewed in (402,600)). There are distinct advantages and disadvantages to this approach. First, the obvious disadvantage is that inhibition of a cellular activity that is essential for cell survival or growth may be detrimental to the host, so such proteins may not be suitable as antiviral targets. However, particularly with acute infections such as influenza, the short duration of therapy may allow for temporary loss of a cellular function without harming the host. The major advantage of targeting a host factor over a viral factor is that resistance is much less likely to develop. Also, there is greater opportunity for host-directed compounds to have broad-spectrum activity as many viruses may rely on the same host function. For example, HSP90 inhibitors have been shown to inhibit influenza virus⁸⁵ and other viruses including hepatitis C virus and Ebola virus.^{469,623} Several inhibitors of enzymes in the *de novo* pyrimidine synthesis pathway have been shown to inhibit the replication of a wide range of viruses, including influenza virus,^{48,280,705} presumably because virus replication is particularly dependent on large pyrimidine pools. Inhibitors of receptor tyrosine kinases have also been shown to inhibit influenza virus replication as well as other viruses.^{348,349} The identification of the target of a novel compound is not always easy, but a cellular target is strongly suggested if the compound can inhibit viruses belonging to different families and/or shows species-specific activity. This is the case with a compound shown to block replication of both influenza viruses and several paramyxoviruses,³⁴⁷ and future identification of the target may reveal an important virus–host interaction. Likewise, known inhibitors of host factors or signaling pathways identified as critical for influenza virus replication could be repurposed as antivirals or at least chemical probes for investigating the function of the virus–host interaction. Inhibitors of the following cellular factors have all been shown to inhibit influenza virus growth: MEK, CAMK2B, vATPase, and CLK1.^{145,325,341,536} Rather than inhibiting the activity of a required host protein, it is also feasible for an antiviral compound to act by activating a cellular factor with antiviral activity, as shown by chemical activation of REDD1 expression, which decreases growth of both influenza and vesicular stomatitis viruses.⁴²³

PERSPECTIVES

Human influenza viruses were first isolated in 1933, and since that time they have been studied extensively. Extraordinary progress has been made in elucidating the components of the virus and in understanding the medical consequences of an influenza virus infection. Many of these discoveries have had implications far beyond the influenza virus field and have sparked new developments in disciplines such as immunology and protein structure as well as furthering our basic understanding of viruses in general. For example, the ability of virus to agglutinate red blood cells (hemagglutination) was first recognized as a property associated with influenza virus, hence the name of its major surface glycoprotein. With the discovery that this phenomenon extends to other viruses (e.g., measles virus, rubella virus), it became the basis for viral diagnostic tests, allowing for easy detection of virus or of protective antibody (hemagglutination inhibition) in patient sera. The influenza virus neuraminidase was also the first enzyme found to be

associated with any animal virus, even before it was recognized that viruses encode their own polymerases, including those with reverse transcriptase activity. The discovery of interferon by Isaacs and Lindenmann in 1957 was as a result of studying infection with heat-inactivated influenza virus, and structural analyses of the HA and NA proteins helped to lay the foundation for the exploration of structure/function relationships of large, biologically active proteins. Today, the intensity of studying influenza and influenza viruses has not diminished and a PubMed search yields approximately 65,000 entries (at the time this chapter was written).

Many approaches that served us well in the past have now been superseded by newer techniques, but their contribution to our current knowledge should not be overlooked. The superb collections of temperature-sensitive mutants obtained and characterized by Akira Sugiura in Japan and by Christoph Scholtissek and Rudolf Rott in Germany made it possible to study the genetics of the virus on a gene-by-gene level, and thus allowed the field to take a giant step forward. The sequencing of these influenza virus proteins and RNAs was an effort of months, if not years. Now this can be done in a matter of hours, and since the last edition of this book, there has been a 20-fold increase in the number of influenza virus sequences submitted to GenBank, which now number almost 200,000. We also have exciting new molecular technologies (including reverse genetics) that have allowed us to obtain an excellent understanding of the virus on a molecular level and to learn how it has changed over the years. Using this technology, we have even been able to resurrect the 1918 pandemic influenza virus from sequenced RNA fragments and to study its pathogenicity in an animal model.

What are the challenges for the future? With the threat of yet another pandemic influenza virus emerging, a detailed molecular understanding of virus–host interactions is needed in order to know how best to disable the virus. Perhaps one of the most pressing questions is, what makes an influenza virus transmissible from human to human and from animal to animal? This aspect has been notoriously difficult to study and will require the use of complex animal models. On a molecular level it will be important to learn more about the cell's signaling pathways and how they are modulated during influenza virus replication. What makes the virus a pathogen in one species and not in another? How does the virus affect the host immune response, and is it in turn affected in any way? What role does the age of a person (child, adult, elderly) and conditions/diseases (pregnancy, obesity, diabetes) play in influenza virus replication? What are the complicating factors (coinfection with other viral/bacterial agents, environmental changes) in an influenza virus infection? And last but not least, we need to address the question of host genetics in influenza virus infection and in virus infections in general. Which genetic makeup (polymorphisms and gene expression profiles) determines susceptibility to (and recovery from) influenza virus infection in humans and animals?

These efforts will need to be accompanied by the development of reliable and rapid diagnostic tests and safe and broadly effective antivirals. As we begin to obtain a better understanding of the host factors involved in influenza virus replication, it presents the opportunity to use these host factors as new antiviral drug targets. Potentially, this approach can lead to the development of broad-spectrum antivirals that can be used to treat

not only influenza but also other viral diseases. Since the isolation and characterization of broadly protective monoclonal antibodies directed against conserved portions of the HA, it is now possible to design new immunogens that may serve as vaccine constructs. Such universal influenza vaccines may avoid annual revaccinations against influenza and provide protection against intrasubtype variants and possibly even against strains belonging to different subtypes. In a new pandemic outbreak the availability of such tools will be imperative. It is likely that answers to these challenges will come from a vigorous basic science enterprise, which has brought us a long way in the past several decades of influenza virus research.

Perspectives

INTRODUCTION

Influenza viruses (family *Orthomyxoviridae*) cause highly contagious respiratory disease with potentially fatal outcomes. Symptoms include fever, headache, cough, sore throat, nasal congestion, sneezing, and body aches. Influenza viruses also cause local epidemics or pandemics (worldwide outbreaks) with significant infection rates. Although the economic burden of influenza is most prominent during pandemics, the combined annual costs of seasonal epidemics due to sick days, emergency department visits, and medications are significant. With the realization that avian influenza viruses can be directly transmitted to humans, influenza viruses are now considered a major, global health threat.

Technologies such as reverse genetics¹⁴⁹⁶ have allowed the routine manipulation of influenza viral genomes. In addition, large-scale sequencing of viral genomes in combination with improved tools for sequence analysis, and other technologies—including yeast two-hybrid screens, small interfering RNA (siRNA)-mediated screens, and transcriptomics, proteomics, metabolomics, and lipidomics studies—are being used to discover the viral and cellular factors that control influenza virus replication, interspecies transmission, and pathogenesis. Despite recent advances, much still needs to be learned about the molecular determinants of these events.

NOMENCLATURE

Influenza viruses belong to the *Orthomyxoviridae* family. This family comprises five genera: *Influenzavirus A*; *Influenzavirus B*; *Influenzavirus C*; *Thogotovirus*, which includes *Thogoto virus* and *Dhori virus*; and *Isavirus*, which includes infectious salmon anemia virus (ISAV; see the International Committee on Taxonomy of Viruses website: <http://www.ictvonline.org>).^{520,1358}

Influenza A viruses are further classified into subtypes based on the antigenicity of their HA and NA molecules; currently, 17 HA subtypes (H1–H17) and 9 NA subtypes (N1–N9) are known. The present nomenclature system¹ includes type of virus, host of origin (except for humans), geographic site of isolation, strain number, and year of isolation, followed by the antigenic description of the HA and NA subtypes in parenthesis; for viruses isolated before 2000, the year should be given as two digits; for viruses isolated in 2000 or later, the year should be given as four digits. For example, A/swine/Iowa/15/30 (H1N1) describes an influenza A virus isolated from a pig in Iowa in 1930 with a strain number of 15 and an H1N1 subtype. Antigenic subtypes have not been identified for influenza

B and C viruses. Thogoto virus, Dhori virus, and ISAV do not cross-react antigenically.

Seroarcheology

Retrospective seroepidemiologic analysis, or seroarcheology, has provided information about influenza virus outbreaks that preceded the virologic techniques currently used to unequivocally identify infectious agents. Early studies suggested that the pandemic of 1889 to 1891 was caused by a virus of the H2N2 subtype, whereas that of 1900 had been attributed to an H3N8 strain.^{1326,1327,1435,1531,1719} More recent re-evaluation of the data indicates that the 1889 to 1891 pandemic was caused by an H3-like virus, and there is no compelling evidence that links the H2 subtype to a pandemic other than that of 1957.⁴⁴² The latter conclusion is substantiated by the lack of protection among those who were at least 80 years old during the 1957 H2 pandemic. Seroarcheology has also linked the 1918/1919 pandemic to an H1 virus, a finding that has been confirmed by sequence determination of influenza virus RNA from the lung tissues of victims.¹⁷¹² Studies using antibodies to the NA protein suggest that in the late 1800s, viruses of the N8 subtype were circulating and later replaced by N1 and N2 subtype viruses. Thus, during the 1900s, only a limited number of virus subtypes (H1N1, H2N2, H3N2, H3N8) was established in humans. Reassortant H1N2 viruses emerged in humans in 2001 and circulated in 2002 and 2003, but have not been isolated from humans since early 2004.

Virus Isolation

In 1930, the first swine influenza virus, A/swine/Iowa/30, was isolated,¹⁸⁶³ but it was not until 1933 that the first human virus was isolated by Wilson Smith, Sir Christopher Andrewes, and Sir Patrick Laidlaw of the National Institute for Medical Research in London, England. These investigators inoculated ferrets intranasally with human nasopharyngeal washes from an influenza patient. The animals exhibited an influenza-like disease, and the virus was transmitted to cage mates. One of their junior colleagues (later Sir Charles Stuart-Harris) became infected by these experimentally infected animals; the virus was subsequently isolated from him.¹⁹⁰⁷ Because it was the first human influenza virus, it was named influenza A virus. In 1940, an antigenically distinct virus was isolated and named type B virus (B/Lee/40).⁵⁵¹ The first influenza C virus was isolated in 1947.²⁰⁵⁴ “Fowl plague” was first described in 1878 as a disease that affected chickens in Italy. The causative agent was isolated in 1902 (A/chicken/Brescia/1902 [H7N7]); however, it was not until 1955 that Schafer recognized fowl plague virus as an influenza virus.¹⁷⁹²

Virus Propagation

Influenza viruses were first propagated in embryonated hens' eggs,²⁰² which continue to be the most widely used system for vaccine production, although cell-culture systems are now also in use (see later discussion). Avian and equine strains of influenza A viruses can be isolated from the allantoic cavity of 10- to 11-day-old embryonated eggs after 2 to 3 days of incubation at 33°C to 37°C. Human influenza viruses have also been isolated from clinical samples inoculated into the allantoic or amniotic cavity of eggs and incubation at 33°C to 34°C. However, recent human viruses are difficult to isolate from embryonated eggs. Influenza virus growth in embryonated eggs leads

to the selection of antigenic variants that are characterized by mutations in the HA protein^{202,992,1738,1739,1800} (see also Host Cell-Mediated Selection of Antigenic Variants section). Influenza C viruses amplify in the amniotic, but not allantoic, cavity of eggs and are usually grown for 5 days in 7- to 8-day-old embryonated eggs.

Influenza viruses can also be propagated in cell culture. Madin-Darby canine kidney (MDCK) cells support the efficient replication of many influenza A and B viruses and are used to isolate viruses from humans.^{2071,2072} Although many influenza viruses can grow in African green monkey kidney (Vero) cells,⁶⁶⁰ they do so less efficiently than in MDCK cells. Cell culture systems based on MDCK,⁷³⁰ Vero,¹⁰⁵⁵ and PER.C6 (human primary embryonic retinoblast)^{1197,1620} cells have been developed for influenza virus vaccine production, and MDCK and Vero cell-based vaccines are approved in Europe for use in humans; MDCK cell-based vaccines are now also approved in the U.S. Influenza viruses also replicate in a number of primary cell cultures, including monkey, calf, hamster, and chicken kidney cells, as well as in chicken embryo fibroblasts and primary human epithelial cells. With the exception of primary human airway epithelium and kidney cells, most cell culture systems require the addition of trypsin to cleave the HA protein of human viruses (except highly pathogenic H5N1 viruses), a prerequisite for efficient replication.

Replication of influenza viruses in eggs or cell culture is measured by testing the ability of the viruses to agglutinate erythrocytes⁸¹⁴ or by use of molecular biology techniques, such as reverse transcriptase (RT)-polymerase chain reaction (PCR).

EVOLUTION OF INFLUENZA VIRUSES

Influenza viruses evolve via a complex process that involves the accumulation of mutations over time and the rearrangement of viral RNA segments in cells infected with two (or more) different viruses (known as “reassortment”). In wild aquatic birds, avian influenza viruses evolve slowly; while mutations occur, most are not sustained in viral populations since they

do not provide an evolutionary advantage. The exceptions are avian viruses in terrestrial poultry, including highly pathogenic H5N1 viruses, which evolve rapidly [see Outbreaks of Highly Pathogenic Avian Influenza (HPAI) Virus section]. In contrast to most avian influenza viruses, human influenza viruses show detectable net evolution over time.

Evolutionary Rates of Influenza A Viruses

Phylogenetic analyses, together with the finding that viruses of all known HA and NA subtypes are maintained in wild aquatic birds, led to the hypothesis that all mammalian influenza A viruses are derived from one avian influenza virus pool^{647,648–649,881,1864,2214,2221} (Fig. 41.1). At the nucleotide level, the reported mutation rates range from $\sim 5 \times 10^{-4}$ to $\sim 8 \times 10^{-3}$ nucleotide substitutions per site per year.^{198,288,397,538,548,562,648,1233,1870,1985,2214,2221,2289,2359}

At the amino acid level, viruses from wild aquatic birds evolve slower than those from terrestrial poultry, swine, or humans.^{562,647,648–649,1870,1995,2214,2246} The fact that in wild aquatic birds most avian influenza A viruses seem to evolve slowly suggests that they are well adapted to their hosts.^{91,2214} Thus, although mutations may occur with similar frequency compared to other hosts, they do not result in many amino acid changes.⁶⁴⁷ Among avian influenza A viruses, the evolutionary rates are highest for the HA, NA, and NS1 proteins,^{288,1110} possibly reflecting their immunogenic or immunomodulatory functions.

Proteins of mammalian and terrestrial poultry viruses continuously accumulate amino acid substitutions. For human influenza A viruses, the evolutionary rates differ among the proteins, likely reflecting differences in the selective pressure of the host.^{527,1870,2214} For example, the HA protein evolves faster than the PB2, PB1, PA, NP, and M1 proteins, because HA variants may confer a selective advantage by allowing the virus to evade the host immune response. The human M1 and M2 proteins, encoded by overlapping reading frames, are under different selective pressures: For the M1 protein, a higher percentage of changes is silent than for the M2 protein.^{562,881,2214} The M1 protein thus appears to be well adapted to its mammalian

FIGURE 41.1. Influenza A virus reservoir. Wild aquatic birds are the main reservoir of influenza A viruses. Virus transmission has been reported from wild waterfowl to poultry, sea mammals, pigs, horses, and humans. Viruses are also transmitted between pigs and humans, and from poultry to humans. Equine influenza viruses have been transmitted to dogs.

hosts, whereas the M2 protein is under stronger selective pressure. The biologic reason for the selective pressure on the M2 protein is unknown. The two proteins encoded by the NS gene also differ in their evolutionary rates, with NS1 showing more variation between alleles than NS2.^{1000,1987} High evolutionary rates have been reported during the establishment of new virus lineages, for example, the introduction of avian H1N1 influenza viruses into European pigs in 1977,¹²⁷⁴ the emergence of highly pathogenic avian H5N2 influenza viruses in poultry in Mexico in 1993/1994,⁶⁰³ and the emergence of highly pathogenic avian H5N1 influenza viruses in Hong Kong in 1997,²³⁷⁵ which may reflect preferential selection of mutants that provide an advantage in a new host. This process may be facilitated by so-called mutator mutants that lead to increased error rates in the viral replication complex.^{1274,1812,1984,1990}

Host-Specific Lineages, and Geographic Segregation of Influenza A Viruses

Extensive phylogenetic analyses have revealed host-specific virus lineages for several viral genes (e-Fig. 41.1). The phylogenetic trees of the PB2, PA, NP, M, and NS genes are similar in that they can be divided into two major branches consisting of avian and avian-like swine, or classic swine and human influenza viruses, respectively.^{90,562,592,647,648,682,881,1559,1901,2214}

The phylogenetic tree of the PB1 gene differs from those of other influenza virus genes. The PB1 genes of human H1N1 viruses cluster with classic swine viruses, whereas the PB1 genes of human H2N2 and H3N2 viruses form a different sublineage that reflects the introduction in 1957 and 1968 of avian virus PB1 genes into human influenza viruses.^{682,1001,1813,1901,2214} The genes other than the HA and NA of equine H7N7 viruses do not cluster with avian, human, or swine influenza viruses,¹⁹⁰¹ suggesting their early separation into a separate lineage.

The phylogenetic tree of the NS gene is divided into two alleles: A and B.^{1000,1987} All mammalian virus NS genes belong to allele A, whereas avian influenza virus NS genes can belong to allele A or B.^{1000,2091}

The H1 HA genes can be separated into a branch consisting of avian and avian-like swine influenza viruses versus a branch consisting of human and classic swine viruses.^{961,1901} The phylogenetic tree of the H3 HA gene consists of two major branches¹⁹⁰¹: one branch splits into two major subbranches that represent equine/canine and North American avian virus isolates. The second branch can be separated into Eurasian avian viruses, and human and swine H3 HAs that separated from the avian viruses in the 1960s. The human H3 gene has evolved in a single lineage since its introduction into the human population in 1968.^{527,682,2214}

The phylogenetic tree of N1 NA genes shows two major branches that separate into human and classic swine, or Eurasian swine and avian N1 NA genes, respectively.^{516,548,1901} The phylogenetic tree of the N2 NA gene can be divided into a North American avian clade, and a second clade that evolved into Eurasian avian and human virus genes at the beginning of the last century.¹⁹⁰¹

These analyses also reveal that influenza virus genes can be separated by their geographic origin, with a North American and a Eurasian gene pool.^{438,456,1446,1545,1569,2246} These gene pools appear to evolve largely independently, although reassortment between North American and Eurasian viruses has been reported.^{456,1050,1094,1248,1305,2181,2210,2246,2263}

Host-Specific Amino Acids

Recent large-scale sequencing efforts have generated thousands of full-genome influenza viral sequences⁵⁴⁵ (www.ncbi.nlm.nih.gov/genomes/FLU/FLU.html; www.fludb.org; www.gisaid.org). The comparison of viral proteins derived from different host species has revealed signature amino acids at specific positions that distinguish human, avian, and swine virus isolates.^{10,19,276,516,533,562,603,648,881,1037,1205,1233,1399,1400,1559,1603,1686,1812,1840,1986,2214} In particular, comparative studies have identified a number of human-like signature amino acids in highly pathogenic avian H5N1 influenza viruses,^{19,276,533,1037,1205,1400,1686,1840} the pandemic 1918 virus,^{276,533,1399,1603,1713,2049} and 2009 pandemic H1N1 viruses,¹⁶⁰³ which may play a role in adaptation to humans. For some of these signature amino acids, a role in pathogenicity has been demonstrated (see Molecular Determinants of Host Range Restriction and Pathogenesis section).

Computational analyses of viral sequences have also identified differences in mutation patterns and codon usage between human and avian influenza viruses.^{460,663,927,1698,2258} Such approaches may improve our understanding of influenza virus evolution.

Quasispecies

The high error rate of the replication complex of RNA viruses results in the generation and co-circulation of different genetic variants within a host organism.⁴³³ If the biologic fitness of a quasispecies is comparable to that of the predominant variant, the minor variant may be maintained in virus populations at low frequencies.¹¹⁴⁹ In the event of host or environmental pressure (including innate and adaptive immune responses, and selective pressure resulting from a host change or antiviral pressure), greater genetic diversity may increase the probability for variants that are better adapted to the changed environment. In such a scenario, quasispecies may be selected and become the dominant virus population. In the past, the detection of quasispecies was cumbersome due to the detection limits of conventional sequencing techniques. With advances in deep sequencing and mass spectrometry analyses, minor sequence variants can be detected more easily. These techniques are now used to assess the levels of quasispecies and mixed infections,^{620,1118,1786,2318} which may provide critical information on the emergence of novel variants. For example, deep sequencing revealed that variants of the 2009 pandemic H1N1 virus possessed mutations in the antigenic site¹¹¹⁸; it will be interesting to assess whether these variants become dominant in the future.

Evolution in Influenza B and C Viruses

Significant differences in evolutionary rates exist for influenza A, B, and C viruses.^{289,527,812,1000,1100,1236,1534} Type B viruses, and especially type C viruses, evolve more slowly than influenza A viruses. Type B and C viruses seem to be near or at an evolutionary equilibrium in humans; in contrast, the genes of type A human viruses were introduced from birds²²¹⁴ and have not reached an equilibrium in humans. Influenza A viruses in humans evolve along single lineages, which suggests evolution by clonal selection¹⁹⁶ and limited co-circulation of sublineages. Co-circulation of sublineages has been shown over only limited periods.^{372,527} In contrast, the evolution of influenza B and C viruses is characterized by the co-circulation of antigenically and genetically distinct lineages over extended periods of time.^{197,2305} For influenza B viruses, two lineages—B/Victoria

(represented by B/Victoria/2/87) and B/Yamagata (represented by B/Yamagata/16/88)—have been co-circulating for about 25 years with changing patterns of prevalence and geographic distribution.^{812,960,1236,1360,1488,1623,1757,1759}

INFLUENZA VIRUS GENETICS

Reassortment

Reassortment is the rearrangement of viral gene segments in cells infected with two (or more) different influenza viruses (Fig. 41.2). Reassortment between two viruses can theoretically result in $256 \cdot 2^8$ different gene variations (i.e., the two parental genotypes and 254 new gene combinations). Reassortment occurs for influenza A, B, and C viruses, but has not been observed among the different types of influenza viruses.

The importance of reassortment to the generation of new influenza virus strains is highlighted by the last three pandemics: reassortant viruses that contained HA, PB1, and NA, or HA and PB1 segments of avian virus origin in a human genetic background, caused the so-called Asian Influenza in 1957 and

Hong Kong Influenza in 1968.^{1001,1155,1813} The H1N1 pandemic in 2009 was caused by a reassortant virus that possessed North American avian-like PB2 and PA segments, Eurasian avian-like swine NA and M segments, a human H3N2-like PB1 segment, and classic swine H1N1-like HA, NP, and NS segments.^{388,604,1903,2094} Six of these segments (all but the NA and M segments) were derived from triple human/avian/swine reassortant viruses that emerged in 1997/1998 and have spread throughout the North American pig populations^{972,1570,2209,2373} (see Influenza in Swine section). These viruses caused a few cases of self-sustained human infections without further spread.^{78,2055,2163} Hence, at least two sequential reassortment events were critical in the emergence of the new pandemic strain: first, the generation of a triple reassortment swine virus; and second, the introduction into this virus of Eurasian avian-like NA and M segments. In addition, the highly pathogenic H5N1 viruses currently circulating in Southeast Asia arose from multiple reassortment events among avian influenza viruses, and continue to reassort.^{278,279,281,449,677,678,681,826,1089,1205,1247,1296,1491,1902,2157,2290} [see Outbreaks of Highly Pathogenic Avian Influenza (HPAI) Viruses section].

In addition to reassortment events that create new lineages or pandemics, reassortment can create novel viruses that circulate for a limited time period.^{752,846,873,1034,1174,1182,2005,2187,2277,2285,2358}

For human influenza viruses, intrasubtypic reassortment may be more important than previously thought,^{829,1235,1479,1481,1482,1700} and may have led to the epidemics observed with reassorted H1N1 viruses in 1947 and 1951,^{1030,1482} reassorted H2N2 viruses in 1967,¹²³⁵ and reassorted H3N2 viruses in 1997 and 2003.^{829,1700}

In experimental settings, multiple reassortants can be generated between highly pathogenic avian H5N1 and human H3N2^{284,905,1198,1301} or 2009 pandemic H1N1 viruses¹⁵⁴⁸; between 2009 pandemic H1N1 and seasonal H1N1¹⁵⁴⁷ or avian H9N2 viruses²⁰⁰⁶; or between human H3N2 and genetically distant equine H7N7 viruses.¹¹⁹⁹ However, not all gene combinations can be generated experimentally, and others may not be compatible in nature. Nonetheless, these studies demonstrate the propensity of influenza viruses for reassortment.

Recombination

Recombination has been detected in influenza virus segments that contain genetic material from more than one origin. For negative-sense RNA viruses, homologous recombination is uncommon; however, recombination by “template switching” can occur and lead to increased biologic fitness of the virus. For example, the insertion of 54 nucleotides of 28S ribosomal RNA into the A/turkey/Oregon/71 HA gene increased HA cleavability.¹⁰²⁰ Similarly, an A/seal/Massachusetts/1/80 variant contained a 60-nucleotide insertion (likely derived from the NP gene) in the HA gene, which also enhanced HA cleavability.¹⁵⁷⁶ Avian influenza viruses of low pathogenicity have converted to high pathogenicity following the insertion of 21 nucleotides of the M segment^{161,815,1614} or 30 nucleotides of the NP segment¹⁹⁸⁹ into the HA segment. Serial egg passages of an A/WSN/33 virus containing a 24-amino-acid deletion in the NA stalk led to variants that replicated efficiently in eggs.¹⁴⁰¹ The NA stalk of these variants contained sequences that originated from the PB1, PB2, and NP genes. In another example, a virus contained an NP gene that likely resulted from intracistronic recombination between two NP

FIGURE 41.2. Reassortment. Co-infection of cells with two different influenza A viruses can theoretically result in 256 different genotypes (2^8 , i.e., the two parental genotypes and 254 new genotypes). Reassortment is a major mechanism for the generation of pandemic influenza viruses, as demonstrated in 1957 (Asian influenza), 1968 (Hong Kong influenza), and 2009 [A(H1N1)pdm09].

segments.¹⁷⁴⁷ In this case, it is unclear whether the recombination event provided a selective advantage to the virus. Moreover, attempts to generate influenza virus by providing an *in vitro* synthesized RNA encoding a viral segment yielded several recombinant viruses.¹²¹ Recently, computational analyses of influenza viral sequences identified several potential recombination events among influenza viral genes^{152,770,771}; however, some of these may in fact represent laboratory-generated artifacts.

Reverse Genetics

Highly efficient systems are now in place for the artificial generation of influenza A,^{542,1496} B,^{824,897} and C^{362,1448} viruses, and of Thogotovirus.²¹⁷³ These systems rely on the intracellular synthesis of influenza viral RNAs by a cellular enzyme, RNA polymerase I, that transcribes ribosomal RNA in the nucleus of eukaryotic cells. The influenza viral segments are encoded by cDNAs flanked by the RNA polymerase I promoter and the RNA polymerase I terminator or a ribozyme sequence. RNA polymerase I transcription in transfected cells results in the efficient synthesis of RNA transcripts with defined 5' ends, whereas the integrity of the 3' ends is achieved by using the nucleotide-specific RNA polymerase I terminator¹⁴⁹⁶ or a self-cleaving ribozyme.⁵⁴² To generate influenza viruses, cells are transfected with eight plasmids to provide all eight viral RNAs, as well as with four plasmids for the expression of the polymerase and NP proteins that are required to initiate viral replication. Although this approach requires the co-transfection of cells with 12 plasmids, it is highly efficient, routinely yielding 10⁸ plaque-forming units of influenza A virus per mL of cell culture supernatant. In one modification, both the RNA polymerase I transcripts (for viral RNA synthesis) and the RNA polymerase II transcripts (for mRNA synthesis) are derived from the same template,⁸²⁵ which reduces the number of plasmids required for virus generation to eight. In another modification, the eight RNA polymerase I transcription units for the eight viral RNAs are combined,¹⁴⁹⁰ allowing the generation of the entire viral genome from a single plasmid. In addition, a reverse genetics system based on T7 RNA polymerase has been established.⁴⁰⁷ These systems have revolutionized influenza virus research [reviewed in^{1492–1494,1497}] in that they allow researchers to study the functions of viral proteins in the viral life cycle, as well as their roles in pathogenesis and host range restriction. Moreover, these systems are now invaluable tools for the generation of influenza virus vaccines and vaccine vectors. In fact, reverse genetics has permitted the generation of inactivated and live vaccine strains for H5N1 viruses that could not have been produced by conventional approaches.

INFLUENZA IN HUMANS—PAST PANDEMICS AND THE H5N1 EPIDEMIC

Pandemics are outbreaks that impact large geographic areas and large portions of the population in a short period of time. Pandemics are the most dramatic manifestation of influenza, attacking 20% to 40% of the world population and causing significant mortality. Influenza pandemics have occurred in 10- to 40-year intervals, although reliable records only date back to the 1918/1919 pandemic (Fig. 41.3). The cumulative death

toll of epidemics in interpandemic periods, although less dramatic, parallel those of pandemics.

The Pandemic of 1918/1919—Spanish Influenza (H1N1)

The pandemic of 1918/1919 remains unprecedented in its severity. It killed more people than World War I and reduced life expectancy in the United States by 10 years. AIDS has killed 25 million people in its first 25 years—the Spanish influenza killed an equal number in 25 weeks (from September 1918 to March 1919). This pandemic occurred in three waves. In the spring of 1918, a mild respiratory disease started at Fort Funston, Kansas (now Fort Riley), attributed to a soldier that had been cleaning pig pens.³⁶⁶ There is no mention of the presence of poultry in the camp at that time. The disease spread among soldiers from Fort Funston along the rail lines to other military bases and cities in the United States and on troopships to Europe.¹⁶¹⁹ This first wave was highly contagious but caused few deaths and received limited attention in most parts of the world. In Spain, a neutral country without news censorship, the outbreak was covered extensively by news media and was soon referred to as the “Spanish influenza.” In late August, a second wave with a higher mortality rate started, probably in western France, from where it spread around the world; this wave peaked between September and November. During that time, death tolls reached more than 10,000 people per week in some US cities. About one-third of the US population became sick,⁵⁵⁷ and the mortality rate was estimated to be over 2.5%, compared to less than 0.1% in typical influenza outbreaks. These figures reflect the impact of the pandemic on the developed world; death rates are believed to have been significantly higher in African and Asian countries. In some isolated populations, the mortality rate reached 70%, likely because of the lack of previous exposure to influenza virus. A third wave of similar impact to that of the second wave struck in late 1918/early 1919.

Typically, the onset of symptoms was sudden, with high fever, severe headache and myalgia, cough, pharyngitis, and coryza. Pathologic findings were mostly restricted to the respiratory tract; death was due to pneumonia and respiratory failure.²²⁵⁵ There was no evidence of systemic viral infection.²²⁵⁵ Most patients died of secondary bacterial pneumonia,^{190,302,1272,1420} but some showed massive acute pulmonary hemorrhage or pulmonary edema,²²⁵⁵ indicating the extreme virulence of the virus. The high rate of bacterial complications may be attributed to the lack of antibiotics in 1918 and 1919.

Age-specific morbidity was similar to that of other pandemics, with children younger than 15 years experiencing the highest infection rates.⁹⁴⁰ The mortality pattern, however, differed significantly from that of other influenza virus outbreaks. In typical influenza outbreaks, the highest death rates are observed in very young children and in the elderly. In 1918 and 1919, many deaths occurred among young adults. The death rate for the 15- to 35-year-old age group was 20 times higher in 1918 than in previous years^{1229,1880} and persons younger than 65 years accounted for more than 99% of excess deaths.¹⁸⁸⁰

The origin of the 1918/1919 virus remains an enigma. In 1927, E. Jordan⁹⁴⁰ published a comprehensive review of the origin of the pandemic. He found no evidence that the disease had originated in China. He also evaluated two reports that described local outbreaks of respiratory infections associated with high mortality and heliotrope cyanosis, which was

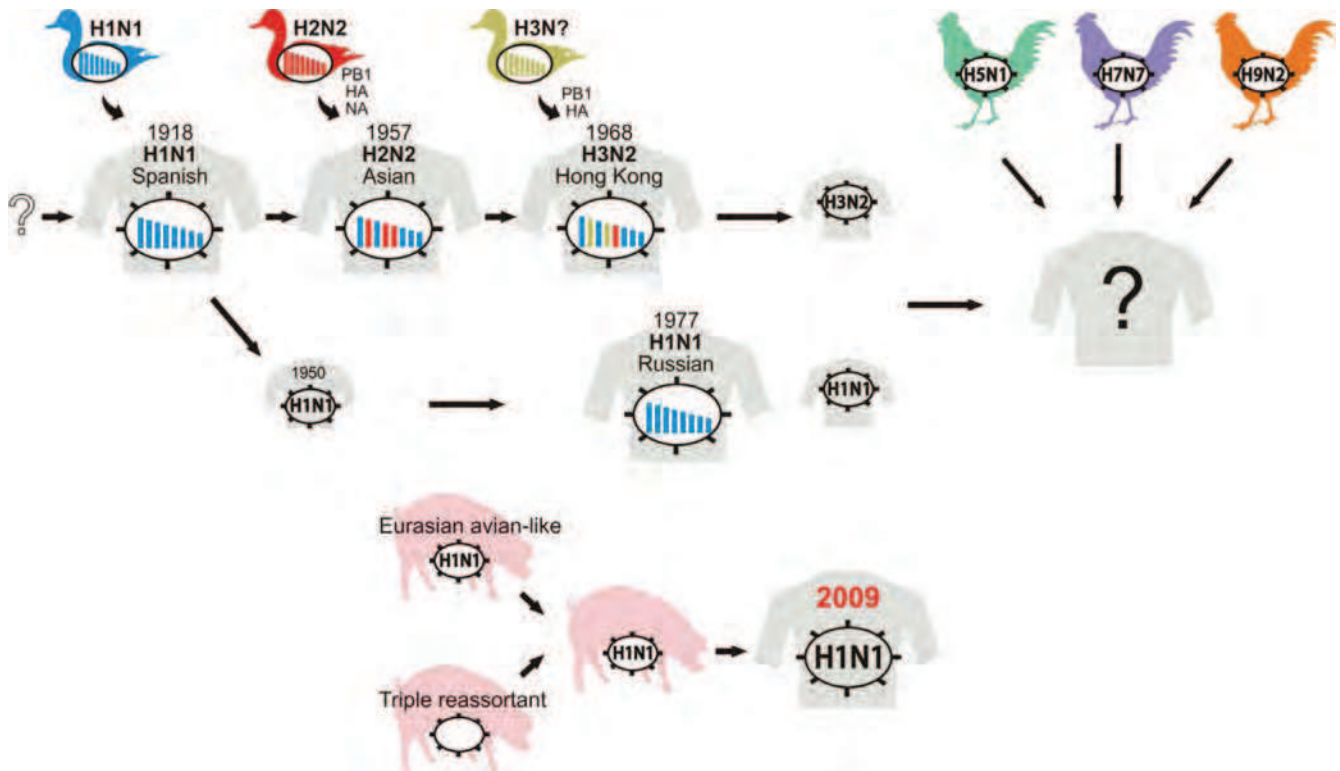

FIGURE 41.3. Evolution of influenza A viruses circulating in humans. An avian H1N1 virus caused the Spanish influenza in 1918. Its descendants circulated until the mid-1950s and reemerged in 1977, causing the Russian influenza. Viruses of this lineage continued to circulate in human populations until 2009. The Asian influenza in 1957 was caused by an H2N2 virus that acquired its HA, NA, and PB1 genes from an avian H2N2 virus. A similar reassortment event in 1968 resulted in the introduction of avian virus HA and PB1 genes into the human population, causing the Hong Kong influenza. H3N2 viruses circulate in humans to this day. In 2009, reassortment of triple-reassortant swine viruses and Eurasian avian-like swine viruses (which donated the NA and M segments) resulted in the A(H1N1)pdm09 virus (see Fig. 41.5 for more details), which replaced the then-circulating H1N1 viruses.

observed during the 1918/1919 outbreak, in army camps in Étaples in Northern France in the winter of 1916 and in Aldershot barracks in March 1917. He dismissed both reports because the disease did not spread but disappeared after short episodes. The most likely origin of the pandemic was Haskell County, Kansas, where Dr. L. Miner noticed an outbreak of influenza in early February 1918 that differed from other influenza outbreaks in that it attacked young, healthy adults, who developed pneumonia that often led to sudden death.⁷⁵ Dr. Miner's observations were published in *Public Health Reports* (now *Morbidity and Mortality Weekly Reports*) and appear to be the first reference to the 1918/1919 pandemic. Men from Haskell County reported to Fort Funston for military training, where they arrived between February 26 and March 2, 1918. On March 4, the first soldier at the camp was reported ill; within a 3-week period, more than 1,100 soldiers at the camp required hospitalization.

Seroarcheology suggests that the causative agent was an H1N1 virus. This was confirmed by Taubenberger et al., who recovered viral RNA from formalin-fixed, paraffin-embedded tissues from two soldiers who died in 1918,^{1712,2048} and from an Inuit female of unknown age whose body was exhumed from a mass grave in the permafrost of Alaska.¹⁷¹² RT-PCR amplification of the viral RNAs provided viral gene sequences.²⁰⁴⁸ Phylogenetic analyses revealed that 1918 Spanish influenza

virus proteins contain both “avian-like” and “human-like” signature amino acids (see Host-Specific Amino Acids section).²⁰⁴⁹ Further analysis suggested that the 1918 virus genes were not directly transmitted from an avian species, but likely circulated in a mammalian host for several years before causing the pandemic outbreak in 1918.^{33,1901,2258}

Reconstitution of the 1918 Spanish influenza virus by use of reverse genetics demonstrated its high pathogenicity in mice, ferrets, and nonhuman primates.^{1068,2102,2107,2206} In nonhuman primates, the virus caused severe respiratory disease with extensive edema and hemorrhagic exudates,¹⁰⁶⁸ similar to reports of human infections. Rapid recruitment of macrophages and neutrophils was observed in the lungs of infected mice,^{1068,1639,2105} in line with findings of altered immune responses in infected mice⁹⁸³ and nonhuman primates.¹⁰⁶⁸ Further studies indicated a role in virulence for several viral proteins (see later discussion and Molecular Determinants of Host Range Restriction and Pathogenesis section): HA,^{981,1070,1607,2103,2104–2105} the polymerase proteins, particularly PB1,^{1607,2102,2131,2206} NS1,^{132,612} and PB1-F2.¹³⁵⁶ Two viral proteins, HA and PB2, are critical for the transmissibility of this virus in ferrets.²¹³¹ In contrast to its high virulence in humans, mice, ferrets, and nonhuman primates, the 1918 virus is of low pathogenicity in pigs,²²³¹ chickens, and mallard ducks.⁵³

Unlike contemporary human viruses, reassortants possessing the 1918 HA, or HA and NA, genes are highly pathogenic in mice.^{981,1070,1607,2103,2104–2105} Reassortant viruses containing the 1918 HA gene induce high levels of macrophage-derived cytokines and chemokines, which stimulate inflammatory cell infiltration and hemorrhage^{981,1070,2105}—hallmarks of Spanish influenza infection. The underlying mechanism is unknown. Structural analysis of the HA protein revealed that although most of the amino acids of the receptor-binding pocket are avian-like, the amino acid at position 190 (an aspartic acid as found in human viruses) is responsible for HA binding to human respiratory cell-surface receptors,^{590,1972} as previously predicted.¹³³⁰ Consistent with this structural finding, the 1918 HA protein preferentially recognizes human-type receptors in receptor-binding assays.⁶²⁸ The replacement of two amino acids in the 1918 HA (D190E and D225G) abolished respiratory droplet transmission in ferrets, although the mutant virus maintained its lethal phenotype in infected animals.²¹⁰⁷

The NS1 protein is an interferon antagonist and, as such, is considered a determinant of pathogenicity. A recombinant virus containing the 1918 virus NS gene in the background of A/WSN/33 (H1N1) virus⁷⁷ is attenuated in mice; however, microarray studies of samples obtained from mice infected with this virus indicate that the 1918 virus NS gene blocks the expression of interferon (IFN)-regulated genes more efficiently than does the parental A/WSN/33,^{132,612} suggesting a role for NS1 in viral pathogenicity. This is further supported by the finding that the PDZ ligand domain motif of the 1918 NS1 protein (formed by the four C-terminal amino acids of this protein; see Molecular Determinants of Host Range Restriction and Pathogenesis section) increased the virulence in the background of A/WSN/33 virus.⁸⁹⁸ In addition, the PB1-F2 protein (see Molecular Determinants of Host Range Restriction and Pathogenesis section for more information) of the 1918 virus contributes to virulence.^{340,1356} Further studies using recombinant viruses found no significant contributions of the 1918 M and NP genes to viral pathogenicity.^{2103,2104}

The Pandemic of 1957—Asian Influenza (H2N2)

This pandemic originated in the Southern Chinese province of Guizhou in February 1957 and spread to Hunan Province and to Singapore and Hong Kong in March and April, respectively.¹⁹⁸⁰ In May 1957, the causative agent of the outbreak, an influenza A virus of the H2N2 subtype, was isolated in Japan. A first wave struck the United States and United Kingdom in October 1957, and was followed by a second wave in January 1958. The infection rate was highest in 5- to 19-year-olds,⁶³⁰ where it exceeded 50%. Both waves were characterized by heightened mortality, with about 70,000 deaths in the United States^{1531,1880} and more than 1 million deaths worldwide.

Genetic and biochemical analyses indicated that the 1957 pandemic virus originated from reassortment between human and avian viruses (Fig. 41.3). It contained H2 HA and N2 NA genes of avian virus origin.^{1791,1813} Because the pandemic virus did not appear to be extraordinarily pathogenic, the increased mortality is attributed to the lack of preexisting immunity among humans to the new surface glycoproteins of this virus. In addition to avian virus HA and NA genes, the 1957 pandemic virus also possessed a PB1 gene of avian virus origin.¹⁰⁰¹ The contribution of this gene segment to the pathogenicity of the pandemic 1957 virus is unknown.

Influenza viruses of the H2 subtype continue to be isolated from avian species, and were isolated from pigs in 2006.¹²⁹² Since vaccination against H2N2 viruses was discontinued in the late 1960s, only individuals 40 years of age or older have protective antibodies against this subtype,¹⁴⁶¹ suggesting that a new pandemic by an H2 virus would cause appreciable excess morbidity and mortality in a large section of the population. However, avian H2N2 viruses have evolved slowly, so that the pandemic H2N2 vaccine from 1957 still protects mice against recently circulating avian or swine H2 strains^{274,997}; this vaccine may thus provide a first line of defense in the event of an H2N2 pandemic.

The Pandemic of 1968—Hong Kong Influenza (H3N2)

Eleven years after their emergence, viruses of the H2N2 subtype were completely replaced by those of the H3N2 subtype (Fig. 41.3). The first signs of a new pandemic emerged in southern Asia in the summer of 1968.³³⁰ A virus of the H3N2 subtype was isolated in Hong Kong in July 1968, which soon spread around the world. The attack rates reached 40% and were highest in 10- to 14-year-olds. The excess mortality was estimated to be 33,800 in the United States.¹⁵³¹

The 1968 pandemic virus contained an avian virus HA protein of the H3 subtype that shared less than 30% sequence homology with its predecessor. However, preexisting antibodies to the N2 protein in human populations likely accounted for the moderate severity of the outbreak. In addition to an avian H3 gene,¹⁸¹³ the 1968 pandemic strain also acquired an avian virus PB1 gene,¹⁰⁰¹ as did the 1957 pandemic strain. It is unknown whether the introduction of an avian virus PB1 gene into the human population contributed to the pathogenicity of the 1968 pandemic virus. The HA and PB1 genes originated from viruses of the Eurasian avian lineage, consistent with epidemiologic findings that southern China was the likely origin of the pandemic.

The Reemergence of H1N1 Viruses in 1977—Russian Influenza

The first signs of a new influenza virus outbreak were noted in Tianjin, China, in May 1977. From November 1977 through the end of 1978, young adults around the world suffered from an influenza virus outbreak in the Union of Soviet Socialist Republics and in China.^{1114,2361} The United States experienced a similar outbreak in mid-January 1978, and outbreaks in other countries occurred during the following winter. Among school-age children, the attack rates were more than 50%. Morbidity was almost exclusively limited to persons younger than 25 years, suggesting that older individuals were protected by preexisting immunity. This assumption was proven when the causative agent was identified as an influenza H1N1 virus (A/USSR/77) closely related to strains that had circulated in the early 1950s.^{1016,1091,1469,1814} (Fig. 41.3). This close relationship and the lack of mutations that are typically acquired during replication argue against maintenance of the virus in a nonhuman species. It is now believed that accidental release of this virus started the pandemic. In contrast to 1968, when the newly emerging H3N2 viruses replaced the circulating H2N2 viruses, replacement of H3N2 viruses did not occur in 1977 with the reemergence

of H1N1 viruses. Instead, both H1N1 and H3N2 viruses continue to circulate to this day.

The H5N1 Outbreak

Although not yet a pandemic, the outbreak of H5N1 viruses across Asia and the Middle East deserves discussion here because of its socioeconomic implications and clinical threat. The virus first emerged on geese farms in 1996 in Guangdong Province, China.^{1883,2290} In May 1997 in Hong Kong, a 3-year-old boy was infected and succumbed to the infection.^{320,322,1993}

The causative agent was an H5N1 virus of entirely avian origin. This incident marked the first reported transmission of a wholly avian influenza virus to a human with fatal outcome.^{320,322} In November and December 1997, 17 additional cases were reported, 5 of which had fatal outcomes. No conclusive evidence of human-to-human transmission exists. These human cases accompanied an outbreak of influenza in live bird markets in Hong Kong. Because most infected individuals had contact with poultry prior to their illness, officials ordered the culling of all poultry in Hong Kong's live bird markets, resulting in appreciable economic losses. This intervention proved successful, and no further cases were reported until 2003. Further human infections were probably prevented when poultry stocks were depopulated again in May 2001 and February and April 2002, after highly pathogenic H5N1 viruses reemerged in live bird markets. However, in February 2003, two Hong Kong residents were infected with H5N1 virus.¹⁶²⁵ A 9-year-old boy became sick when his family traveled to Fujian Province in mainland China and was hospitalized in Hong Kong. He recovered from an H5N1 virus infection, but his 33-year-old father succumbed to the disease. The 7-year-old daughter died in a hospital in China during the family's travels; the cause of her death was not determined.

A new outbreak of H5N1 virus started in July 2003 in poultry in Vietnam, Indonesia, and Thailand, although it lacked official recognition at the time. It has since spread to more than 60 Asian, European, Middle Eastern, and African countries, and has led to the depopulation or death of more than 100 million poultry. H5N1 viruses are now enzootic in poultry populations in China, Indonesia, Vietnam, Egypt, India, and Bangladesh⁴³² (<http://www.fao.org/news/story/en/item/66118/icode/>), and continue to cause outbreaks in the Middle East and sporadic infections in Europe. In addition to far-reaching economic consequences, direct avian-to-human transmission of highly pathogenic avian viruses has caused widespread public apprehension. As of February 1, 2013, 615 cases with 364 fatalities had been reported, resulting in a mortality rate of ~60% (http://www.who.int/influenza/human_animal_interface/EN_GIP_20130201CumulativeNumberH5N1cases.pdf). Most human infections have occurred in Indonesia, Egypt, and Vietnam. The number of reported human infections was highest in 2006 (115 infections that resulted in 79 fatalities), and has declined to 48 cases (with 24 fatalities) in 2010. It is not known if this decline can be attributed to changes in human behavior and/or viral properties, or represents a random fluctuation.

Although H5N1 viruses have not yet acquired the ability to spread efficiently among humans, isolated cases of human-to-human transmission may have occurred.^{626,958,959,1573,1574,1829,2084,2116,2118,2191,2245} However, most of these clusters involved family members living in the same household, and infection may have occurred through exposure to a common source (such

as sick or dead poultry), rather than human-to-human transmission. Overall, transmission of H5N1 viruses to humans appears to be rare and primarily associated with contact with sick or dead poultry,^{32,38,283,426,519,957,1429,2084,2133,2371} although other modes of infection (for example, through virus-contaminated feces or water) have been considered as well.^{398,958,1829,2169,2170,2244}

During the 1997 and 2003 H5N1 outbreaks in Hong Kong, there was no evidence of systemic viral infection in infected individuals.^{1625,2069} More recent H5N1 viruses, however, appear to cause systemic infection in humans^{398,399,676,2112,2113}; virus has been recovered from not only respiratory organs, but also stool and cerebrospinal fluid (CSF), while viral sequences and/or antigens have been detected in brain neurons; in epithelial cells of the intestinal tract; in heart, spleen, kidney, and liver; and in the placenta and fetus of a pregnant women infected with an H5N1 virus. The detection of viral sequences and antigen in the intestinal tract is consistent with the expression of avian-like virus receptors in the human gut,¹⁸⁷³ the *ex vivo* infection of gut tissue with an H5N1 virus,¹⁸⁷³ and reports of gastrointestinal symptoms.^{37,797,2084,2345} In H5N1 virus-infected patients, acute respiratory distress syndrome (ARDS) with diffuse alveolar damage is common.^{38,95,310,591,676,1087,1509,1650,1662,2069,2084,2112,2331,2357} Virus and/or antigen binding has been detected to nonciliated epithelial cells in the bronchioles, and type II pneumocytes and macrophages in the alveoli.^{413,676,1219,1521,1662,2113,2139} Type II pneumocytes differentiate to type I pneumocytes, which are critical for gas exchange in the alveoli; the infection of type II pneumocytes may thus result in more severe lung damage. The observed pattern of virus binding is also in accordance with the detection of avian-type receptors on some bronchiolar and alveolar cells.^{1521,1662,1854,2139} However, H5N1 viruses also replicate in *ex vivo* organ cultures of the upper respiratory tract.¹⁵²¹ The levels of proinflammatory cytokines are higher in individuals infected with H5N1 viruses than in those infected with seasonal influenza virus, and higher in fatal than in nonfatal cases of H5N1 infection.^{399,1625} The pathology in humans is in line with cell-culture studies that demonstrate increased levels of proinflammatory cytokines upon H5N1 infection,^{266,298,300,611,848,1131,1180,2190,2368} animal infection studies that show increased pathology, viral targeting of type II pneumocytes,^{1064,1733,2139} and stronger innate immune responses upon H5N1 virus infection compared to infection with control viruses [see Outbreaks of Highly Pathogenic Avian Influenza (HPAI) Virus section]. Collectively, the available data suggest that the high mortality in humans results from a combination of high virus loads and the induction of high levels of proinflammatory pathways, which may culminate in extensive alveolar damage.

Some of the currently circulating H5N1 viruses are resistant to the antiviral drugs amantadine and rimantadine.^{299,1686} Most H5N1 viruses are sensitive to the NA inhibitors oseltamivir and zanamivir¹¹⁸⁶; however, oseltamivir-resistant viruses have been isolated from H5N1 virus-infected patients treated with this drug^{400,1164} (http://www.emro.who.int/csr/media/pdf/ai_press_22_01_07.pdf). These viruses contain an amino acid substitution at position 274 or 294 of the NA protein. It is of major concern that two patients treated with oseltamivir subsequently shed drug-resistant viruses and eventually died.⁴⁰⁰

The H1N1 Pandemic in 2009

The first reports of an influenza-like outbreak in a small Mexican town can be dated to mid-February 2009 (<http://www.guardian.co.uk/world/2009/apr/27/swine-flu-search-outbreak-source>).

In early April, Mexican public health authorities began investigating and informed international agencies of a possible outbreak. In mid-April, genetically similar swine-origin H1N1 influenza A viruses were detected in several specimens collected in southern California^{253,388} and Mexico.^{249,258,331,332} The novel virus spread rapidly among humans across different continents, prompting the World Health Organization (WHO) to declare Phase 6 (pandemic phase, which is characterized by community-level outbreaks with human-to-human spread in at least two countries in more than one WHO region) on June 12, 2009.^{333,2351} The WHO soon adopted the name “pandemic (H1N1) 2009” for the novel virus (<http://www.who.int/csr/disease/swineflu/en/index.html>) but now suggests A(H1N1)pdm09 (<http://afluidiary.blogspot.com/2011/10/who-call-it-ah1n1pdm09.html>). This outbreak marked the first pandemic in more than 4 decades. Viruses of the H1N1 subtype have circulated in humans since 1977; hence, pandemics are not limited to viruses with novel HA subtypes (i.e., those not recently circulating in humans), but can be caused by viruses possessing HA subtypes that are circulating in human populations, as long as the novel HA is antigenically distant enough from its predecessor to escape human immune responses.

The pandemic virus spread rapidly.¹⁸⁹ The southern hemisphere (where the influenza season lasts from May to September) experienced significant pandemic influenza activity from May to mid-July of 2009; the United States experienced a first wave in May and June, and a second wave that started in late August and peaked during the second week of October. The novel virus soon dominated the previously circulating seasonal H1N1 viruses; in fact, more than 99% of influenza A viruses subtyped during the winter of 2009/2010 were novel A(H1N1)pdm09 viruses.²⁵⁶ For the United States, the Centers for Disease Control and Prevention (CDC) estimated a total of 61 million infections with 274,000 hospitalizations and 12,470 deaths between April 2009 and April 2010 (http://www.cdc.gov/h1n1flu/estimates_2009_h1n1.htm). However, about 30,000 influenza-related deaths occur in the United States during each interpandemic season, indicating a low case-fatality rate for infections with the A(H1N1)pdm09 virus. Morbidity and mortality rates differed significantly between age groups^{311,469,556,705,1676,1677,1770,2310}; children experienced a low case-fatality rate. Nonetheless, an appreciable number of small children died from infection with the A(H1N1)pdm09 virus. In contrast to seasonal influenza epidemics, the elderly experienced a low infection, but high case-fatality rate. The low infection rate among the elderly can be explained by serum cross-reactivity between A(H1N1)pdm09 viruses and close descendants of the pandemic 1918 virus,^{252,311,705,734,864,890} which is a consequence of shared antigenic epitopes between the HA proteins of these two viruses.^{604,664,860,890,1093,1309,1903,2229,2287,2307} Those aged 5–59 years accounted for the highest absolute numbers of deaths and cases of pneumonia, in contrast to seasonal outbreaks.^{311,469} Epidemiologic data identified several factors associated with an increased risk of severe disease, including pregnancy (particularly in the last trimester), underlying chronic conditions, and obesity.^{57,244,246,259,388,469,705,706,909,910,1254,1261,2351}

Human infections with A(H1N1)pdm09 viruses typically caused mild upper respiratory tract illnesses with fever, cough, sore throat, shortness of breath, headache, and rhinorrhea.^{223,244,259,388,469,705,706,1635} In addition, gastrointestinal

symptoms (which are unusual with seasonal influenza infections) were reported in some cases. In some patients, respiratory and multiorgan failure occurred, leading to death. These severe infections caused diffuse alveolar damage, hemorrhagic interstitial pneumonitis, and peribronchiolar and perivascular lymphocytic infiltrates^{86,625,684,705,706,1635,1847,1927} (Fig. 41.4), similar to human infections with avian H5N1 viruses (see The H5N1 Outbreak section). These findings are in line with animal infection studies that demonstrated more severe lung lesions and higher lung virus titers in mice, ferrets, and nonhuman primates infected with A(H1N1)pdm09 virus compared with seasonal influenza virus infections.^{101,890,1302,1442,1637,1772,2126} In nonhuman primates, viral antigen was detected in type I and II pneumocytes,⁸⁹⁰ as has been reported for some human cases of A(H1N1)pdm09 infection,⁶⁸⁴ and for nonhuman primates infected with avian H5N1 influenza virus.⁷⁶ Efficient replication in the lungs with infection of type I and II pneumocytes (which likely contributes to the observed alveolar damage) may thus be a hallmark of severe influenza virus infections. In many human A(H1N1)pdm09 cases, bacterial co-infections were detected^{243,625,705,706,914,1254,1345,1599,1635} (Fig. 41.4), a finding that has rekindled interest in the contribution of bacterial infections to influenza-related morbidity and mortality.

Sequence and phylogenetic analyses revealed that the A(H1N1)pdm09 virus possesses PB2 and PA genes of North American avian virus origin; a PB1 gene of human H3N2 virus origin; HA (H1), NP, and NS genes of classic swine virus origin; and NA (N1) and M genes of Eurasian avian virus origin^{388,604,1903,2094} (Figs. 41.3 and 41.5). A(H1N1)pdm09 viruses do not possess amino acids associated with high virulence in mammals.^{388,556,604,1495,1903,1931} In line with its presumed porcine origin, the virus replicates efficiently, but without symptoms, in experimentally infected miniature pigs⁸⁹⁰ and transmits efficiently among pigs.¹⁷⁸ Other studies have demonstrated efficient transmission of A(H1N1)pdm09 viruses in ferrets.^{890,1302,1442,1637} In nature, A(H1N1)pdm09 viruses have also infected turkeys,¹²³ cats,^{1256,1362,1935} dogs,⁴⁵⁹ and ferrets.²⁰¹⁵ The widespread circulation of A(H1N1)pdm09 viruses may lead to reassortment with other human, swine, or avian influenza viruses. In fact, the pandemic virus has infected pigs^{511,827,1417} and reassortment with swine influenza viruses has been reported.^{1418,1949,2158} Experimental studies demonstrated ready reassortment of A(H1N1)pdm09 viruses with avian H5N1,^{1548,1921} avian H9N2,²⁰⁰⁶ or contemporary human influenza viruses^{1547,1819,1921}; some of these reassortants showed increased replicative ability than the A(H1N1)pdm09 parental viruses.^{1547,1819,1921}

Concerns over a potentially severe pandemic spurred the development of vaccines for the new pandemic virus. In the United States and Europe, the first vaccines were approved in September 2009.^{251,254,933} These vaccines proved to be safe and efficacious. Protective antibody titers were obtained with a single dose of vaccine, despite earlier concerns that two doses may be required; however, two doses were recommended for children younger than 10 years of age, due to lack of preexisting immunity.^{1215,1664,2376} A(H1N1)pdm09 viruses have now replaced seasonal H1N1 virus as part of annual, trivalent influenza vaccines (see also Vaccines section). On August 10, 2011, the WHO declared an end to the pandemic (http://www.who.int/mediacentre/news/statements/2010/h1n1_ypc_20100810/en/index.html). The A(H1N1)pdm09

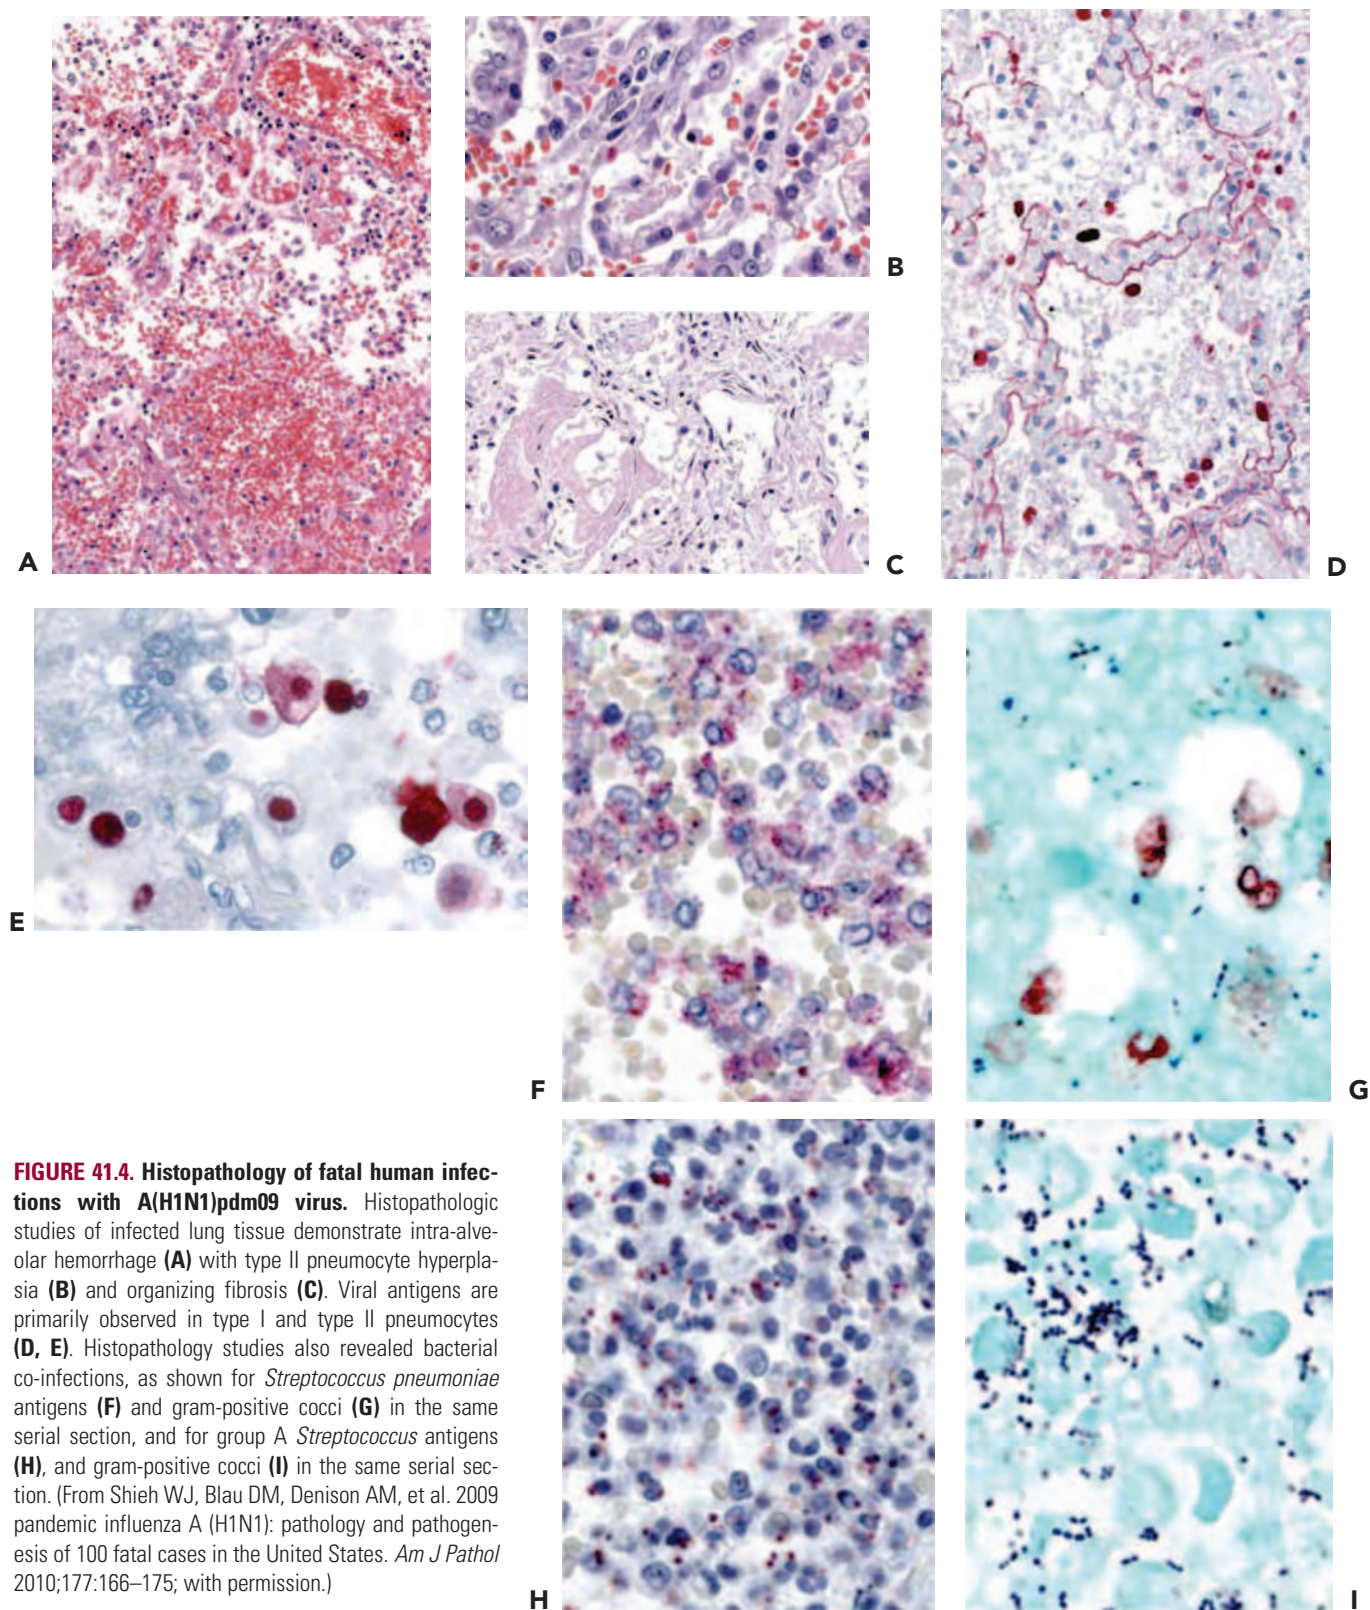

FIGURE 41.4. Histopathology of fatal human infections with A(H1N1)pdm09 virus. Histopathologic studies of infected lung tissue demonstrate intra-alveolar hemorrhage (**A**) with type II pneumocyte hyperplasia (**B**) and organizing fibrosis (**C**). Viral antigens are primarily observed in type I and type II pneumocytes (**D**, **E**). Histopathology studies also revealed bacterial co-infections, as shown for *Streptococcus pneumoniae* antigens (**F**) and gram-positive cocci (**G**) in the same serial section, and for group A *Streptococcus* antigens (**H**), and gram-positive cocci (**I**) in the same serial section. (From Shieh WJ, Blau DM, Denison AM, et al. 2009 pandemic influenza A (H1N1): pathology and pathogenesis of 100 fatal cases in the United States. *Am J Pathol* 2010;177:166–175; with permission.)

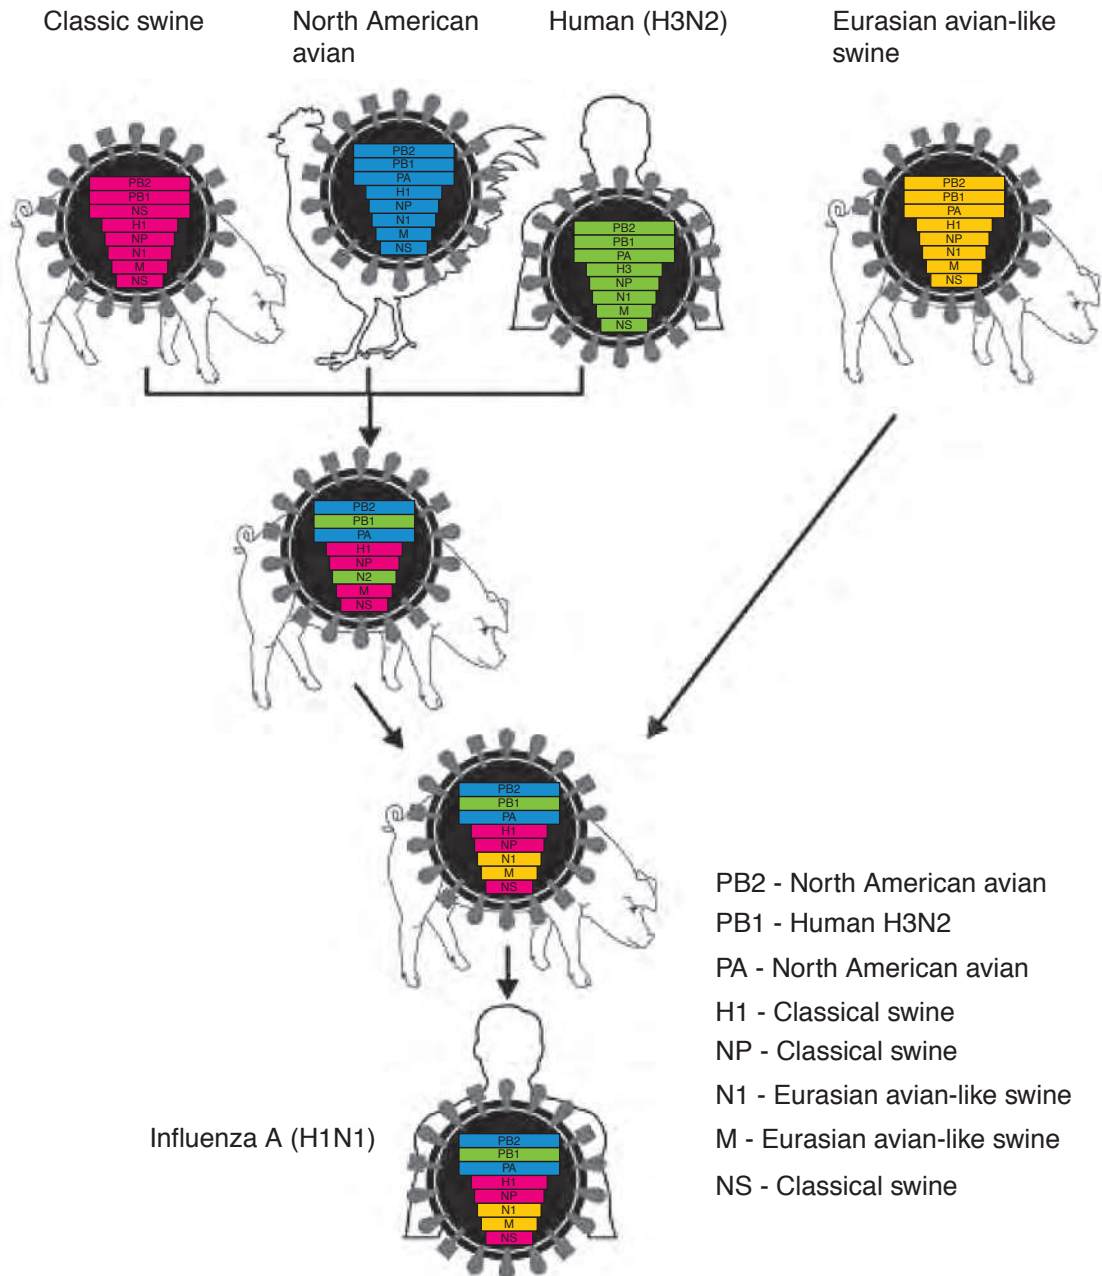

FIGURE 41.5. Genesis of A(H1N1)pdm09 virus. In the late 1990s, reassortment between classical swine, North American avian, and human H3N2 viruses resulted in triple-reassortant H3N2 and H1N2 swine viruses that became established in North American pig populations (see Influenza in Swine—North America section). Reassortment of these viruses with a Eurasian avian-like swine virus led to the emergence of the A(H1N1)pdm09 virus. (From Neumann G, Noda T, Kawaoka Y. Emergence and pandemic potential of swine-origin H1N1 influenza virus. *Nature* 2009;459:931–939, with permission.)

virus will likely continue to circulate as a seasonal influenza virus.

INFLUENZA IN HUMANS—EPIDEMIOLOGY

Since 1977, seasonal H1N1 and H3N2 viruses have been circulating together with influenza B viruses; in 2009, the seasonal H1N1 viruses were largely replaced by A(H1N1)pdm09

viruses. The prevalence of these groups of viruses varies geographically and temporally, making influenza virus epidemiology complex.

Several studies have assessed the global circulation patterns of influenza viruses^{532,1480,1700}; some analyses indicate that human H3N2 and H1N1 epidemic strains originate from Southeast Asia, from where they are seeded into temperate regions.^{94,263,1766} Temporally overlapping epidemics in Southeast Asia result in continuous virus circulation.¹⁷⁶⁶ Even

though influenza viruses circulate in tropical regions throughout the year,^{1766,2155,2257} seasonality has been observed in these areas, although it is less pronounced than in temperate climates.^{1430,1610,1766} In the temperate regions of North America and Europe, multiple variants may circulate during the early epidemic period, which are replaced by a dominant variant at the peak of an epidemic.³⁶¹

The epidemiology of human influenza viruses is defined by their constant antigenic variation to escape the host immune response. In contrast to most other respiratory viruses, influenza viruses possess two different mechanisms that allow them to reinfect humans and cause disease—antigenic drift and antigenic shift.

Antigenic Drift

Antigenic drift occurs as a result of point mutations in influenza A and B viruses and refers to minor, gradual, antigenic changes in the HA or NA proteins. Influenza A virus drift variants result from the positive selection of spontaneous mutants by neutralizing antibodies.^{204,1666} These variants can then no longer be neutralized by antibodies to the “parental” strains. Antigenic drift has also been observed among influenza viruses in terrestrial poultry, although to a lesser extent than in humans.¹¹⁷⁰

Mutations in the human virus HA or NA amino acid sequence occur at a frequency of less than 1% per year. Nevertheless, antigenic drift variants can cause epidemics and typically prevail for 1 to 5 years before being replaced by a different variant.

Antigenic Drift of the HA Protein

The HA protein is the major antigenic component of the virus. Its function and structure are described in more detail in Chapter 40. X-ray crystallography, comparative sequence analysis, and the characterization of escape mutants have identified five antigenic domains (A–E) for H3 HAs^{619,1066,2223,2247,2248} (Fig. 41.6A): Site A is formed by a protruding loop (amino acids 140–146); site B is formed by another loop (amino acids 155–160) and an α -helix (amino acids 188–198) and is situated at the membrane distal end of HA; site C is located at the base of the globular domain in the antiparallel sheet of HA1; site D is situated near the trimeric interface of the globular head domains; and site E lies near the bottom of the globular distal domain between sites C and A. For H1 viruses, the antigenic sites are designated Ca1, Ca2, Cb, Sa, and Sb²³⁹ (Fig. 41.6B). Some overlap exists among antigenic sites.^{239,374} For H5 HAs, X-ray crystallographic structures have been resolved for the HA proteins of an H5N1¹⁹⁷⁰ and an H5N3⁷⁰⁷ virus, which allowed the mapping of antigenic escape variants obtained with H5N2,^{995,996} H5N9,¹⁶⁴⁹ and H5N1^{995,1204,1762} viruses. Depending on the virus and antibodies used for the analysis, three to five antigenic sites that confer neutralization were identified, some of which overlap with antigenic sites in H3 or H1 HA proteins.

Numerous studies have analyzed antigenic drift in nature.^{156,157,395,1100,1150,1387,1472,1634,1799,1801,1892,2293,2294} Minor antigenic heterogeneity among the viruses is detectable at any time,^{64,395,1586,1888,1967} whereas larger differences, detectable in hemagglutination-inhibition tests, usually require the accumulation of mutations over a 1- to 5-year period.^{930,1363,2150} However, single point mutations in one HA antigenic site can

be sufficient for antigenic variation.^{2247,2248,2252} The H3 HA has drifted more rapidly than the H1 and H2 HAs,⁵²⁷ resulting in the frequent replacement of antigenic variants. Although human H1 and H3 HAs evolve in single lineages,^{204,2085} H1 antigenic drift variants co-circulate, yielding a phylogenetic tree with more side branches.^{527,2085} The faster evolution of H3 HAs has necessitated the update of the H3 vaccine component 23 times since 1972, whereas the H1 component has been replaced only eight times^{236,756} (<http://www.who.int/csr/disease/influenza/vaccinerecommendations1/en/index.html>). The HA of A(H1N1)pdm09 viruses has not yet drifted significantly,⁵⁶³ presumably due to the lack of selective pressure in a predominantly naïve population.

In the laboratory, antigenic drift can be mimicked by virus propagation in the presence of monoclonal antibodies to a single site, with a frequency of variant selection of 1 in 10⁵.^{328,618,1137,1151–1153,1470,1471,2144,2215,2222,2223,2224} The selection of variants in the presence of antibodies to several antigenic sites is likely a rare event. Accordingly, the selection of drift variants in humans who have polyclonal responses is difficult to imagine. Postinfection human sera have a limited antibody repertoire,²¹⁹³ and some animal sera are essentially monoclonal.¹¹³⁶ Therefore, the selection of antigenic drift variants may be a sequential event with the stepwise accumulation of mutations through different individuals.

Recently, a new hypothesis has been proposed for antigenic drift.⁷⁸⁴ Escape variants selected with neutralizing antibodies showed increased affinity to cellular receptors; passage of such variants in naïve mice resulted in the loss of high-affinity receptor binding, while this property was maintained in immune mice. These findings suggest interplay between selection by antibody and receptor recognition, at least in the mouse model.

Over the past decade, computational bioinformatics approaches have become an invaluable tool for studying and predicting antigenic drift. Most notably, antigenic cartography now provides an interpretation of antigenic clusters and their relationships, as well as the extent and directionality of antigenic drift.^{547,1900} (Fig. 41.7). Antigenic cartography suggests that antigenic drift of human H3N2 viruses occurs in clusters: while nucleotide changes continue to occur, clusters of antigenically similar variants exist for several years until they are replaced by a new cluster, founded by an antigenic variant that necessitates an update of the vaccine strain.^{58,1077,1078,1766,1900} Hence, the genetic evolution of H3 HA genes is continuing, while its antigenic evolution is punctuated. The same pattern of antigenic jumps likely also exists for human H1 viruses. Antigenic cartography as developed by Smith et al. is now routinely used by the WHO for the selection of vaccine strains.⁴⁹⁹ Other groups have developed similar approaches.^{212,843,2279}

Antigenic drift has also led to the diversification of recent H5 HA proteins into several antigenically and genetically distinguishable clades and subclades; these are described in the Outbreaks of Highly Pathogenic Avian Influenza (HPAI) Virus section.

Antigenic cartography and computational modeling have provided new insight into antigenic drift of human influenza viruses. Computational approaches have also been used to analyze mutation patterns in HA, and have demonstrated that most positively selected amino acid changes map to the antigenic sites.^{41,140,204,638,844,1842,1843,1848}

Crystallographic structures of influenza A virus H3 and H1 HA proteins. **A:** Crystallographic structure of the trimer complex of influenza A virus H3 HA protein (Protein Data Bank #1HGD) showing the locations of the five antigenic epitopes: antigenic site A (amino acids 122, 124, 126, 130–133, 135, 137, 138, 140, 142–146, 150, 152, 168), *red*; antigenic site B (amino acids 128, 129, 155–160, 163–165, 186–190, 196–198), *green*; antigenic site C (amino acids 44–48, 50, 51, 53, 54, 273, 275, 276, 278–280, 294, 297, 299, 300, 304, 305, 307–312), *blue*; antigenic site D (amino acids 96, 102, 103, 117, 121, 167, 170–177, 179, 182, 201, 203, 207–209, 212–219, 226–230, 238, 240, 242, 244, 246–248), *yellow*; antigenic site E (amino acids 57, 59, 62, 63, 67, 75, 78, 80–83, 91, 92, 94, 109, 260–262, 265), *purple*. **B:** Crystallographic structure of the HA protein of A(H1N1)pdm09 virus. Shown is the trimer complex with the antigenic sites Ca (amino acids 140–145, 169–173, 206–208, 224, 225, 238–240), *orange*; Cb (amino acids 79–84), *dark blue*; Sa (amino acids 128, 129, 156–160, 162–167), *red*; Sb (amino acids 187–198), *light blue*. (**B** reproduced from Xu R, Ekiert DC, Krause JC, et al. Structural basis of preexisting immunity to the 2009 H1N1 pandemic influenza virus. *Science* 2010;328:357–360, with permission.)

Antigenic Drift of the NA Protein

The function and structure of this protein are discussed in detail in Chapter 40. In addition to HA, antigenic drift has also been reported for NA^{367,1286,1350,1605,1802} and correlated with amino acid differences in the molecule.³³⁸ Studies with monoclonal antibodies and amino acid sequence analyses have revealed two to three antigenic sites.¹¹ The NA of most influenza A virus subtypes and of influenza B viruses has been crystallized.^{12,1226,2050,2291} The structure contains two major antigenic sites located on the upper surface of the molecule, where they flank the sialic acid-binding site. A possible third antigenic site resides on the bottom of the head; however, it is difficult to imagine how antibodies binding to this site would result in the selection of escape mutants. A more detailed structural analysis of the Fab fragment of a monoclonal antibody (NC41) to N9 NA showed that five peptide loops, located at the rim of the enzyme active site, constitute the epitope.²¹⁰⁰

The second epitope, characterized with monoclonal antibodies to N8 NA, is located at the interface of two adjacent monomers in the tetrameric NA and involves peptide loops on both monomers.¹⁷⁷⁹ Antibodies with this epitope bind only to NA tetramers.

Antigenic Shift

Antigenic shift involves major antigenic changes in which an HA or NA that is antigenically distinct from the circulating variant is introduced into the human population. Typically, antigenic shift is caused by an HA or NA of a new subtype, that is, one that did not circulate in humans prior to the pandemic. The H1N1 pandemic in 2009 was a notable exception since it was caused by a virus of the H1N1 subtype, even though viruses of this subtype had been circulating in humans since 1977. These newly introduced proteins are immunologically distinct from the previously circulating strains and result in

FIGURE 41.7. Antigenic cartography. The map shows seasonal H3N2 viruses from 1968 to 2003. Each *open circle* represents an antiserum used for analysis. Each *colored circle* represents an H3N2 strain tested by using the hemagglutination inhibition assay against the selected antisera. The distances between strains and/or antisera are relative to their antigenic distances (in HI units). The spacing between the grid lines is equivalent to a twofold dilution of antiserum in the HI assay. Typically, fourfold changes in HI titers (i.e., two gridlines in the map) require an update of the vaccine. The different colors represent the antigenic clusters to which the strains belong (HK68, Hong Kong 1968; EN72, England 1972; VI75, Victoria 1975; TX77, Texas 1977; BK79, Bangkok 1979; SI87, Sichuan 1987; BE89, Beijing 1989; BE92, Beijing 1992; WU95, Wuhan 1995; SY97, Sydney 1997; FU02, Fujian 2002). (From Smith DJ, Lapedes AS, de Jong JC, et al. Mapping the antigenic and genetic evolution of influenza virus. *Science* 2004;305:371–376, with permission.)

high infection rates of the novel virus in the immunologically naïve population, leading to pandemics.

Since the beginning of the last century, five antigenic shifts have occurred: in 1918, with the appearance of H1N1 viruses that caused the Spanish influenza; in 1957, when the H1N1 subtype was replaced with H2N2 viruses, causing the Asian influenza; in 1968, when H3N2 viruses replaced the H2N2 subtype, leading to the Hong Kong influenza; in 1977, when the H1N1 subtype reappeared (Russian influenza); and in 2009, when a novel, antigenically distinct H1N1 virus caused a pandemic that largely replaced seasonal H1N1 viruses (see The H1N1 Pandemic in 2009 section). These new subtypes occurred suddenly and at irregular and unpredictable intervals.

The antigenic shift that caused the pandemics in 1957 and 1968 resulted from reassortment between human and avian viruses. By contrast, the A(H1N1)pdm09 virus resulted from reassortment events among swine, avian, and human influenza viruses (see The H1N1 Pandemic in 2009 section). Although not conclusive, phylogenetic evidence suggests that the Spanish influenza was caused by the introduction of an avian-origin virus into the human population.^{77,1712,1713–1715,2048,2049}

Transmission of Avian Influenza Viruses to Humans

Prior to 1997, the direct transmission of avian influenza viruses to humans was not considered a serious human health threat. This assumption was based on findings that avian viruses do not replicate efficiently in experimentally infected humans⁹² and that no severe cases of human infections had been reported during any outbreaks of highly pathogenic avian influenza (HPAI). The differences in receptor-binding specificities between human and avian viruses (for details, see Molecular Determinants of Host Range Restriction and Pathogenesis section) were believed to provide a host range barrier that limited the transmission of avian viruses to humans. Until 1997, only three cases of direct avian-to-human transmission of influenza viruses had been described: (1) an HPAI virus of the H7N5 subtype isolated from a patient with hepatitis in 1959,^{219,409} (2) an H7N7 HPAI virus isolated from a laboratory worker who developed conjunctivitis,²⁰⁵³ and (3) an H7N7 virus of low pathogenicity isolated from a woman who developed conjunctivitis and was likely infected from ducks she kept.^{60,1119} These cases, together with serologic studies,^{1864,1872,2345,2372} demonstrated the potential for avian influenza viruses to be transmitted to humans; however, the true threat of avian-to-human virus transmission was not fully realized until 1997, when avian H5N1 viruses were transmitted to humans in Hong Kong and killed 6 of 18 patients.^{320,322,394,1993,2345}

In 1998 and 1999, H9N2 viruses transmitted from birds to pigs and humans. Five human infections were reported in southern China⁶⁹⁸ and, in March 1999, two children were infected in Hong Kong.^{1227,1626} Both presented with symptoms of typical influenza and recovered. The isolates were genetically similar to those from quail (A/quail/Hong Kong/G1/97 [H9N2]). There was, however, no evidence of human-to-human transmission.²¹¹⁹ During an outbreak of HPAI H7N7 viruses in poultry in the Netherlands in February/March 2003, 89 people were infected, 83 of whom developed conjunctivitis.^{546,1085} Most cases were mild and self-limiting, although a veterinarian developed acute respiratory distress and an ultimately

fatal pneumonia.²¹³⁵ In three cases, human-to-human transmission was documented and antibodies were detected in 59% of those who had contact with infected poultry workers. Also in 2003, a young child in Hong Kong was infected with an H9N2 virus but recovered uneventfully.^{207,297} In November 2003, an H7N2 virus was isolated from an adult in New York who was hospitalized for upper and lower respiratory tract illness, but eventually recovered.^{255,463} In 2004, two people developed conjunctivitis and mild respiratory symptoms after an outbreak of an HPAI H7N3 virus in poultry in Canada.^{815,2111} Additional cases of human infection with avian influenza viruses were detected in the United Kingdom in 2006 and 2007, when H7N3 and H7N2 viruses caused conjunctivitis in one¹⁵¹⁰ and four individuals,⁴⁶³ and in Hong Kong in 2008 and 2009, when genetically different H9N2 viruses were isolated from two immunocompromised patients.²⁹⁷ These findings underscore the potential of H7 and H9 viruses to infect humans, although human-to-human transmission has thus far been limited. In 2004, two cases of human infection with H10N7 virus were reported in Egypt (<http://www.paho.org/english/ad/dpc/cd/eid-eer-07-may-2004.htm>); this subtype has not been isolated in humans before or since.

Highly pathogenic H5N1 viruses have thus far claimed 364 lives in several countries (for more details see The H5N1 Outbreak section). The recent increase in the number of human infections with avian influenza viruses may be a consequence of better surveillance and reporting infrastructure, and/or increased human contacts with poultry and other bird populations.

Vaccines for use in humans for H5 (see Vaccines section), H7,^{275,357,405,906,944,1608} and H9^{275,977} viruses are currently in development. In the United States, the first H5N1 vaccine for human use was approved in April 2007 (<http://www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm112838.htm>). However, due to the antigenic drift of the H5 HA, the cross-protection among the antigenic clades is not optimal without an adjuvant. Likewise, human infections with H7 viruses have been caused by antigenically distinct viruses of the North American and Eurasian lineages, which may necessitate the development of several vaccines based on antigenically different viruses.

Transmission Among Humans

Influenza viruses do not cause persistent or latent infections in immunocompetent individuals; they are maintained in human populations by direct person-to-person spread during acute infections. Seasonal disease patterns have been reported for temperate climate regions^{444,1242,1255}; In the northern hemisphere, epidemics generally peak between January and April, but may flare up as early as December or as late as May.^{532,830,1531} In the southern hemisphere, outbreaks occur between May and September. The low relative indoor humidity during the winter months may prolong the survival of influenza in aerosols^{735,780,781,1263,1793} and contribute the seasonal pattern in the northern hemisphere. However, seasonality is also observed in tropical and subtropical climates^{23,376,402,1181,1431,1766,2155,2308} where increased influenza activity appears to coincide with the onset of the rainy season.^{301,402,440,1431,1703,1704} On a global scale, influenza virus activity is detectable throughout the year,^{1531,1766} and viruses can be isolated in large cities year-round.

The incubation period is 1 to 3 days for influenza A viruses and 1 to 4 days for influenza B viruses.^{550,1191} The most effective means of spread among humans are aerosols.^{1428,2056} Most aerosol droplets formed during sneezing or coughing are less than 2 μm in diameter and are preferentially deposited in the lower airways of the lung^{46,290,1231,1232,1513,2309}; however, normal breathing also produces aerosols.^{471,512,529} Volunteers are readily infected by aerosol transmission¹⁷; the human infectious dose of influenza A virus infection is 0.6 to 3 TCID₅₀ (dose required to infect 50% of tissue culture) when delivered by aerosol,¹⁷ but 127 to 320 TCID₅₀ when delivered intranasally.³⁴⁷ Ferrets are an established animal model for influenza virus transmission studies (reviewed in^{1341,1542}). Recently, guinea pigs have been established as a model for aerosol transmission,^{1265,1434} and have been used to assess the importance of temperature and humidity for influenza virus transmission.^{1264,1266}

Influenza-Related Morbidity and Mortality

The collective burden of interpandemics can be substantial and depends on a variety of factors, as indicated in this section. The average annual death toll during interpandemic seasons is about 20,000 in the United States.

Morbidity

Influenza virus is estimated to cause about 50 million illnesses annually in the United States. Excess hospitalizations of between 50,000 and 200,000 Americans per season have been reported.^{670,1436,1879,1882,2063} The H1N1 pandemic in 2009 is estimated to have caused 274,000 hospitalizations in the United States alone. Direct costs include hospitalizations, medical fees, drugs, and testing, and were estimated in 1986 to be about \$1 billion annually, while indirect costs such as loss of productivity reached \$2 to \$4 billion annually.¹⁸⁰⁶ The temporal curves of individual pandemics are similar in that virus introduction into a community is followed by a relatively sharp, single peak that represents school and workplace absenteeism, which is followed by excess mortality slightly later.¹⁵³¹ Notable exceptions are the pandemics in 1918 and 1957, both of which were characterized by a second, more severe wave.^{941,2047,2185}

A number of studies have documented how influenza virus epidemics reduce school attendance and work productivity, increase doctor's visits and hospitalizations, and can cause increased mortality, particularly among high-risk groups.^{1504,1505,1506} Children younger than two years of age and the elderly have the highest hospitalization rates,^{631,895,1506,1641} reaching 1 per 270 for those older than 65 years, compared to 1 per 2,900 for the 1- to 44-year-old age group.^{68,69} The impact of influenza on the elderly extends beyond influenza and pneumonia to all respiratory conditions as well as to congestive heart failure.¹⁵¹⁶ It is an important cause of respiratory infections in nursing homes.⁶⁹ Among children, 14% to 16% of those seeking medical care for acute respiratory illness or fever are infected with influenza virus.^{635,1668,2272}

During interpandemic seasons, the overall infection rates range from 10% to 20% but can reach 50% in selected age groups or populations. The rate and severity of infection depend on the level of preexisting immunity, age of an individual, and virulence of the virus, all of which vary greatly among outbreaks.^{304,549,629,942,1724} Age-specific attack rates are highest in school-age children, and symptoms

in this age group are usually more severe than in young adults.^{549,629,632,1411,2018} Often, increases in school absenteeism mark the beginning of a new epidemic,⁶³¹ suggesting that school-age children play a critical role in disseminating influenza viruses. Increases in school absenteeism are typically followed by increases in workplace absenteeism. Influenza A viruses of the H1N1 and H3N2 subtypes, as well as influenza B viruses, all cause similar symptoms^{555,1522,1934}; however, the frequency of severe infections is higher with H3N2 viruses.²⁰⁶³ Reinfection with a closely related variant can occur,^{384,385,549,553,554,1924} although the symptoms are usually less severe than those that follow the initial encounter with a particular virus strain.^{384,385,629,1924}

The H1N1 pandemic in 2009 showed a similar pattern to previous pandemics since elderly people (who typically suffer high attack rates) were infected in relatively small numbers; their exposure to the descendants of the 1918 pandemic virus which circulated until 1957 may have provided partial protection against the A(H1N1)pdm09 virus^{252,311,705,734,864,890} (see The H1N1 Pandemic in 2009 section).

Mortality

The increase in mortality during pandemics and epidemics is a hallmark of influenza virus infection. The term “excess mortality” was introduced by William Farr and describes the number of deaths observed during an outbreak in excess of the number of expected mortalities. The number of influenza virus–related deaths, however, is difficult to determine because the death certificate may not indicate influenza as a primary cause of death or because a laboratory diagnosis may not have been performed.

Excess mortality was estimated to be between 20 and 50 million deaths for Spanish influenza worldwide,¹⁶¹⁹ and 70,000, 33,800, and 12,470 deaths in the United States for the Asian influenza, Hong Kong influenza, and H1N1 pandemic in 2009, respectively. Although excess mortality is highest during a pandemic, the cumulative deaths of interpandemic seasons usually exceed those of pandemic years^{1531,1881} (Fig. 41.8). During epidemics, excess mortality is estimated to be more than 20,000 in the United States alone but can exceed 40,000 deaths. In the United States, the annual excess mortality appears to have increased over the last decades, perhaps because of an increasing number of elderly and/or immunocompromised individuals.²⁰⁶³ Excess mortality is typically highest with H3N2 virus infections, whereas H1N1 and type B viruses contribute to smaller extents.^{168,667,1881,2063}

Excess mortality affects all age groups but is highest in those older than 65 years, who account for approximately 90% of excess mortalities during interpandemic seasons.^{69,71,483,1936} This age group has a 100-fold higher mortality rate than those younger than age 65.¹⁸⁷⁹ During the 1968 pandemic, however, people younger than 65 accounted for 50% of influenza virus–related deaths,³⁵⁴ and during the 1918 pandemic, excess mortality rates were extremely high not only in the elderly, but also in young adults.¹⁵³¹ The reasons for these unusual patterns are unknown. The highest risk for pneumonia is seen in the elderly who have cardiovascular and pulmonary conditions⁷¹; other risk factors include metabolic or neoplastic diseases and pregnancy.^{69,70,665,1505} Several other factors associated with increased risk of severe disease have been identified for infections with

A(H1N1)pdm09 viruses (see The H1N1 Pandemic in 2009 section).

EPIZOOLOGY AND PATHOGENESIS IN ANIMALS

Influenza A viruses infect a variety of animals, including humans, birds, swine, horses, and dogs. Occasionally, influenza viruses have been isolated from cats, tigers and leopards, stone martens and Owston civets, whales, seals, mink, and camels. Serologic evidence also suggests exposure of several ruminant, reptile, and amphibian species to immunogens related to influenza viruses (reviewed in¹⁷²³).

Viruses of all known HA and NA subtypes are maintained in aquatic birds, generally without causing disease; therefore, aquatic birds are considered the natural reservoir of influenza A viruses.^{465,807,809,1749,1755,1864,1894,2214,2221} Nonpathogenic viruses of the H5 and H7 subtypes can evolve into highly pathogenic avian strains that cause significant losses to the poultry industry.^{62,225,834,836,1002,1748} Viruses of the H5, H6, and H9 subtypes have established or may be establishing lineages in chickens.^{432,1182,2220} Although human pandemics have been associated with viruses of the H1 to H3 subtypes, the ability of avian viruses of the H5, H7, and H9 subtypes to infect humans has flagged viruses of these subtypes as potential candidates for future influenza pandemics. Influenza B viruses typically replicate in humans but have been isolated from seals.^{1550,1582} Influenza C virus infects humans, swine,^{701,1558,2303,2344} and dogs.^{1310,1558}

Influenza in Birds

The natural reservoir of influenza A viruses are the orders *Anseriformes* (ducks, geese, swans) and *Charadriiformes* (gulls, terns, shorebirds),^{445,1894,2214} although influenza A viruses have been isolated from at least 105 different avian species from 26 different families.^{466,1340,1489,1569,1943,1945} Almost all HA and NA subtypes have been detected in dabbling ducks (*Anas* spp.),^{999,1095,1147,1560,1569,1837,1838,1947,2182,2225} suggesting that these species are the major reservoir of influenza A viruses. In mallard ducks (*Anas platyrhynchos*), viruses of the H3, H4, and H6 subtypes are isolated most frequently; the most prevalent subtypes are H4N6 and H6N2.^{737,1095,1441,1838,2182} In addition, several HA subtypes (including H1, H2, H5, H7, and H9–H12), in combination with several NA subtypes, have been detected in waders of the *Charadriidae* family, suggesting a role for these species in the perpetuation of influenza A viruses. Viruses of the H13 and H16 subtypes appear to circulate only in *Laridae* (gull and tern) species.^{262,999,1094,1441,1569,1633,2142} This observation is consistent with the finding that a gull influenza virus did not replicate efficiently in ducks,⁸⁰² perhaps due to differences in receptor-binding preferences between viruses derived from ducks or *Laridae* species.²³⁰⁶ For the NA gene, N2, N6, and N8 subtypes predominate in ducks, whereas N6 and N9 are prevalent in shorebirds and gulls. Poultry play a critical role in the perpetuation of influenza A viruses; thus, most HA and NA subtypes can be isolated from poultry in live-bird markets.^{195,308,1249,1511,1932,1986,2214,2319}

Surveillance studies have demonstrated seasonal patterns in prevalence; the infection rate of mallard ducks reaches 60%

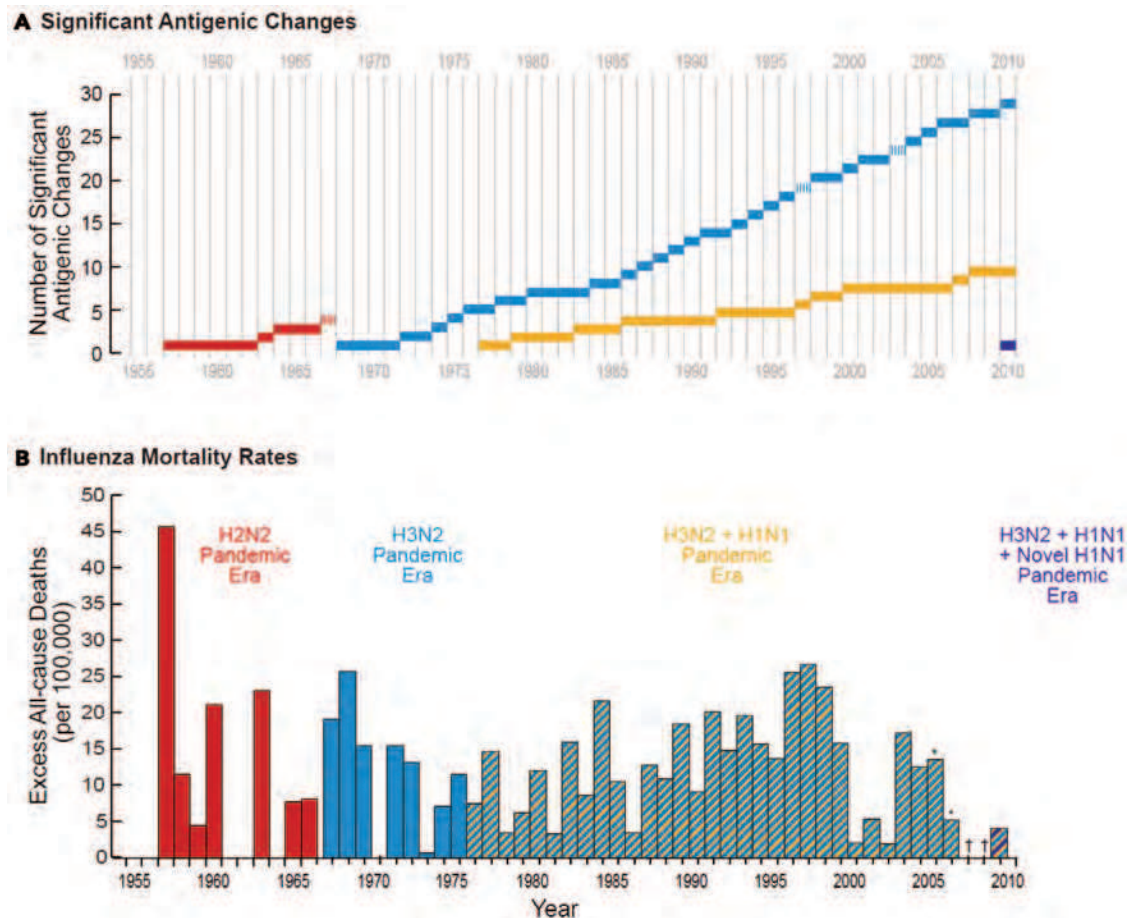

FIGURE 41.8. Influenza virus mortality rates in the United States from 1957 to 2010. Shown are the excess mortality rates per 100,000 persons. *Estimates are given since data are unavailable; †, data unavailable. (Modified from Morens, DM, Taubenberger JK, Fauci AS. 2010. The 2009 H1N1 Pandemic Influenza Virus: What Next? *MBio* 1(4):e00211–10; with permission.)

before the autumn migration, and declines to less than 10% in spring and summer.^{809,811,1095,1441,1560,1569,1945,2182,2214} This pattern may represent the influx of immunologically naïve juveniles every summer, and/or the high population density in marshalling areas before the migration. By contrast, in North American shorebirds, the infection rate is highest in late spring and early summer.¹⁰⁹⁵ Since the prevalence of infection declines along the migration route and is relatively low at the wintering grounds of mallard ducks, geographic patterns in prevalence can be observed (i.e., infection rates are higher at the marshalling areas in the North than at the wintering grounds in the South). Moreover, the prevalence of virus subtypes in the same species changes from year to year.^{811,1095,1838,1945} In particular, cyclic patterns exist in which high rates of prevalence for one subtype in a certain population may be followed by low detection rates in this population in subsequent seasons,^{1095,1838} perhaps due to herd immunity to viruses of the respective subtype.

Reassortment may play a critical role in the evolution of avian influenza viruses with significant contributions of both intrasubtypic reassortment (i.e., reassortment between viruses of the same subtype) and intersubtypic reassortment (i.e., reassortment between viruses of different subtypes),^{278,449,677,678,752,805,1089,1205,1296,1491,2157,2187} and of

reassortment between the North American and Eurasian gene pools, which evolve largely independently, as described earlier.^{388,456,752,1050,1094,1248,1305,2181,2210,2246,2263}

Avian Influenza Viruses of High or Low Pathogenicity

Based on their pathogenicity in chickens, avian influenza viruses are classified as highly pathogenic avian influenza (HPAI) or low pathogenicity avian influenza (LPAI) viruses. LPAI viruses cause mild respiratory disease, depression, and/or a decrease in egg production. For outbreak control purposes, the Office International des Epizooties (OIE) classifies an avian influenza virus as HPAI if it is “lethal for six, seven, or eight of eight 4- to 8-week-old susceptible chickens within 10 days following intravenous inoculation with 0.2 ml of a 1/10 dilution of a bacteria-free, infective allantoic fluid” (OIE Manual of Diagnostic Tests and Vaccines for Terrestrial Animals 2010; accessible at: <http://www.oie.int/en/international-standard-setting/terrestrial-manual/access-online/>), or if it has an intravenous pathogenicity index (IVPI) greater than 1.2 (the IVPI is the mean clinical score of ten 6-week-old chickens intravenously infected). All H5 and H7 viruses of low pathogenicity in chickens with a multibasic sequence at the HA cleavage site are considered highly pathogenic.

Most HPAI viruses have a series of basic amino acids at the HA cleavage site; however, exceptions exist in which viruses with multiple basic amino acids at this site are not highly pathogenic in chickens,^{1002,1171,1257,2012} or highly pathogenic viruses do not possess a conventional HA cleavage site.^{1614,1989} All HPAI viruses known to date belong to the H5 or H7 subtype; however, only a small proportion of all H5 and H7 viruses are highly pathogenic. Historically, disease caused by HPAI viruses was called “Fowl plague.” Viruses that are highly pathogenic for chickens often cause high mortality in turkeys and Japanese quail, but are usually nonpathogenic for ducks and geese, with the exception of some of the recently circulating HPAI H5N1 viruses.

The infection of aquatic birds with LPAI is typically asymptomatic, although even LPAI viruses can cause mild disease in mallards^{945,1147} and swans.²¹²⁸ In ducks, avian viruses replicate in the epithelial cells in the intestinal tract and, to a substantially lesser extent, in cells of the respiratory tract.^{489,2218,2228} These viruses are resistant to the low pH environment they encounter during their passage through the digestive tract. Avian species shed influenza viruses in high concentrations in feces.^{1023,1893,2225,2228} The viruses are relatively stable in water^{1944,1946} and have been isolated from water samples of lakes where wild birds have nested or congregated before migration.^{731,809,810,886} Contaminated water and feces may, therefore, serve as major routes of transmission of LPAI among feral birds.^{810,1885} By contrast, highly pathogenic H5N1 viruses replicate efficiently in the upper respiratory tract of infected birds.^{1006,1982} Human influenza viruses also replicate in the upper respiratory, but not in the intestinal, tract of ducks,²²¹⁸ because they do not recognize efficiently the receptors in duck intestine [sialic acid (Sia) linked to galactose by α 2,3 linkages (Sia α 2,3Gal)].¹⁷⁴⁴

Infection of ducks with some highly pathogenic H5N1 influenza viruses results in systemic infections with high virus titers in the respiratory organs; neurologic symptoms may also be observed.^{488,1049,1982,2148} However, infected birds may die without clinical symptoms.⁴⁸⁸ In experimental infections of several bird species, HPAI H5N1 were not uniformly lethal, and infected animals shed appreciable amounts of viruses, which could facilitate virus spread.^{185,279,1006,1147,1983} A characteristic feature of HPAI H5N1 infection in ducks is that virus titers in oropharyngeal swabs are higher than those in cloacal swabs.^{1006,1983} In chickens, influenza virus infections can result in mortality rates of up to 100%.

Occasionally, avian influenza viruses infect mammalian species. Most of these infections are self-limiting and stable lineages have emerged rarely, such as in pigs in 1979 with the introduction of an avian H1N1 virus.¹⁶³⁰ In mammals, LPAI viruses cause bronchitis, bronchiolitis, and/or pneumonia. Infection with HPAI results in severe, systemic infection (see following discussion and The H5N1 Outbreak section).

Outbreaks of Highly Pathogenic Avian Influenza (HPAI) Viruses

With only three exceptions [A/tern/South Africa/61(H5N3),⁹³ a highly pathogenic H7N1 virus that caused an outbreak in a backyard flock of geese and Muscovy ducks in Italy in 1999/2000,²²⁸ and the so-called Qinghai Lake HPAI H5N1 viruses,^{279,281,1247}], all HPAI outbreaks have occurred in

poultry (Table 41.1). However, H5N2 viruses isolated from an apparently healthy duck and goose possessed an HA cleavage sequence characteristic of HPAI viruses,⁵⁷³ demonstrating that HPAI viruses may emerge in aquatic birds without apparent signs of infection. HPAI is controlled by depopulation and vaccination. Although LPAI viruses had long been considered of negligible risk, it is now clear that HPAI arise from LPAI by mutations.^{62,225,834,836,1002,1748} The major recent outbreaks of HPAI are discussed in the sections that follow (Table 41.1).

H5N1

HPAI H5N1 viruses were first isolated from sick domestic geese in 1996 in Guangdong province.^{1883,2290} Outbreaks of H5N1 HPAI occurred in poultry in Hong Kong from March to May 1997 and again in November 1997.^{1865,1869} These viruses caused high mortality rates (70–100%) in experimentally infected chickens.^{1988,1993} The causative agent was identified as an H5N1 reassortant virus that had acquired its HA gene from an A/goose/Guangdong/1/96 (H5N1,Gs/Gd)-like virus,²²⁹⁰ its NA gene from another avian N1 virus, and its remaining six genes (i.e., PB2, PB1, PA, NP, M, and NS) from other avian viruses.^{681,826} H5N1 HPAI viruses have in common an HA protein with a multibasic sequence at the cleavage site (a characteristic of highly pathogenic viruses).¹⁸⁶⁹ By the same token, many H5N1 isolates possess a shortened NA stalk,²³⁶⁷ a characteristic of viruses adapted in terrestrial poultry.^{116,1331,1869,1988} The H5N1 viruses isolated from Hong Kong patients in 1997 fell into two groups of either high or low pathogenicity in mice.^{593,990,1269,1869} The outbreaks in poultry were accompanied by the first transmissions of wholly avian influenza viruses to humans with fatal outcomes.^{320,322,394,1993} These events, together with the finding that H5N1 infections were widespread in poultry markets in Hong Kong (close to 20% in chickens)¹⁸⁶⁵ prompted the slaughter of all poultry in Hong Kong in late December 1997/early January 1998. The mass slaughter of poultry eliminated HPAI H5N1 viruses from the Hong Kong poultry markets, and no further cases of human infections were reported. However, HPAI H5N1 viruses with an HA gene belonging to the Gs/Gd lineage continued to circulate in avian species in mainland China.¹²⁰⁵ They reappeared in poultry in Hong Kong in 2001 and 2002, and have been isolated from both aquatic and terrestrial poultry since 2001.^{677,1205} The outbreaks in poultry in Hong Kong in 2001 and 2002 were controlled by depopulation, and by vaccination with an H5N2 strain in April 2002. These strict surveillance and vaccination measures have reduced the number of outbreaks of HPAI H5N1 viruses in Hong Kong.

Waterfowl are usually resistant to HPAI viruses; however, in late 2002, waterfowl in Kowloon and Penfold Park, Hong Kong, showed signs of neurologic disease as they succumbed to H5N1 influenza virus infection.^{488,1982} With the exception of A/tern/South Africa/61(H5N3)⁹³ and a highly pathogenic H7N1 virus that caused an outbreak in Muscovy ducks in Italy in 1999/2000,²²⁸ influenza viruses were not known to cause disease in aquatic birds. At the same time as the Kowloon Park outbreak, H5N1 viruses were isolated from dead chickens in retail poultry markets and a local chicken farm.

In April/May 2005, more than 6,000 birds—mostly bar-headed geese, but also brown- and black-headed gulls, ruddy

TABLE 41.1 Outbreaks of Highly Pathogenic Avian Influenza Viruses Since 1955

Virus ^a	Subtype	Comments
A/chicken/Scotland/59	H5N1	Two chicken flocks
A/tern/South Africa/61	H5N3	1,300 common terns
A/turkey/England/63	H7N3	29,000 breeder turkeys
A/turkey/Ontario/7732/66	H5N9	8,100 breeder turkeys
A/chicken/Victoria/76	H7N7	25,000 laying chickens, 17,000 broilers, and 16,000 ducks
A/chicken/Germany/79	H7N7	Outbreaks in former East Germany; numbers unknown
A/turkey/England/199/79	H7N7	3 commercial turkey farms
A/chicken/Pennsylvania/1370/83	H5N2	17 million birds, mostly chickens or turkeys
A/turkey/Ireland/1378/83	H5N8	800 infected turkeys died; 8,640 turkeys, 28,020 chickens and 270,000 ducks were culled
A/chicken/Victoria/85	H7N7	24,000 broiler breeders, 27,000 laying chickens, 69,000 broilers, and 118,518 unspecified chickens
A/turkey/England/50-92/91	H5N1	8,000 turkeys
A/chicken/Victoria/92	H7N3	12,700 broiler breeders and 5,700 ducks
A/chicken/Queensland/95	H7N3	22,000 laying chickens
A/chicken/Puebla/8623-607/94	H5N2	Millions of birds died or were culled; exact numbers are not available
A/chicken/Queretaro/14588-19/95		
A/chicken/Pakistan/447/95	H7N3	3.2 million broilers and broiler breeder chickens
A/chicken/Pakistan/1369-CR2/95		
A/chicken/Hong Kong/220/97	H5N1	1.5 million chickens and other domestic birds; 6 human fatalities (among 18 infected individuals)
A/chicken/New South Wales/1651/97	H7N4	128,000 broiler breeders, 33,000 broilers, and 261 emus
A/chicken/Italy/330/97	H5N2	Chickens, turkeys, guinea fowl, ducks, quail, pigeons, geese, pheasant (all in small numbers)
A/turkey/Italy/4580/99	H7N1	8.1 million laying chickens, 2.7 million meat and breeder turkeys, 2.4 million broiler breeders and broilers, 247,000 guinea fowl, 260,000 quail, ducks, and pheasants; also backyard poultry and ostriches
A/chicken/Chile/4957/2002	H7N2	2 million birds died or were culled
A/grey heron/Hong Kong/861.1/2002	H5N1	Outbreak in wild birds in Hong Kong; over 800,000 domestic birds were culled
A/chicken/Netherlands/1/2003	H7N7	Virus was isolated from 241 poultry farms in The Netherlands, two farms in Belgium, and one farm in Germany; outbreak was controlled by killing more than 30 million birds; one human fatality
A/chicken/Canada/AVFV1/2004	H7N3	Spread to more than 40 commercial poultry farms; outbreak was controlled by culling all 19 million domestic birds in Fraser Valley, British Columbia
A/chicken/Canada/AVFV2/2004		
A/ostrich/South Africa/2004	H5N2	Outbreak in ostriches; 26,000 ostriches were culled to control virus spread
Various H5N1 viruses (since 2003)	H5N1	Outbreak started in July 2003 in poultry in Vietnam, Indonesia, and Thailand and has since spread to a number of Southeast Asian, European, Middle Eastern, and African countries; more than 100 million domestic birds have died or have been culled; mortality has also been observed among wild birds; as of February 1, 2013, 364 human fatalities had been reported (among 615 infected individuals)
A/chicken/North Korea/2005	H7N7	Approximate number of birds affected: 219,000
A/chicken/Saskatchewan/HR-00011/2007	H7N3	Outbreak on a broiler breeding farm in Saskatchewan, Canada; depopulation of all animals on the premise (53,000)
A/chicken/England/1158-11406/2008	H7N7	Outbreak in a laying flock of chickens; death or depopulation of 25,000 animals
A/chicken/Spain/6279-2/2009	H7N7	Outbreak in a layer hen farm; outbreak was stopped through death (~30,000) and depopulation (~278,000) of all animals on the farm

^aOutbreaks that caused significant economic losses (defined as outbreaks that killed or resulted in the slaughter of more than 1 million birds) are shown in bold.

(Modified from Swayne DE, Halvorson DA. Influenza. In: Saif YM, Barnes HJ, Fadly AM, et al., eds. *Diseases of Poultry*. 11th ed. Ames: Iowa State University Press; 2003:135–160.)

shelducks, and great cormorants—died from HPAI H5N1 virus infection at the Qinghai Lake Nature Reserve in Gangcha County, Qinghai Province, China.^{279,281,1247} Although viruses of several genotypes were detected during the outbreak, one genotype was dominant.^{279,281,1247,2370} HPAI H5N1 viruses closely related to the Qinghai Lake isolates have spread through Russia, into Europe, the Middle East, and several African countries. Two factors likely contributed to the dissemination of these viruses: movement of infected poultry and virus spread through migratory birds.^{280,522,1031,1444,1645,1680,1722,1876,2125,2212,2253}

Recent HPAI H5N1 viruses have expanded their geographic range, become enzootic in poultry populations in different parts of the world, more pathogenic in ducks than isolates from 1997,^{1606,1647,1982} and have a broad host range. While HPAI infections are typically limited to terrestrial poultry, the currently circulating H5N1 viruses have been isolated from a number of different wild birds including water birds (order *Anseriformes*) such as ducks, geese, and swans; shore birds (order *Charadriiformes*) such as gulls and waders; small songbirds (order *Passeriformes*) such as sparrows and crows; large wading birds (order *Ciconiiformes*) such as herons, storks, and egrets; several *Ratites* species including ostriches,³⁹⁰ emu, and rhea; and species of several other birds orders.^{279,281,454,488,1082,1221,1247,1287,1839,1982} In addition, HPAI H5N1 viruses have been isolated from carnivores including dogs,^{29,206,325,624,1923} cats,^{29,1064,1104,1105,1733,1922,2120} tigers,^{28,2058} leopards,¹⁰⁰⁵ a stone marten,^{1065,1735} Owston civets¹⁷³⁵ (www.promedmail.org, Archive no. 20080312.0991), and raccoon dogs.¹⁶⁸⁸ Moreover, HPAI H5N1 viruses have been isolated from pigs on several occasions^{1202,1526,1846,2378}; these animals can also be infected experimentally with HPAI H5N1 viruses.^{306,1241,1869} However, pigs do not show symptoms upon infection with HPAI H5N1 viruses.¹²⁴¹ The experimental infection of calves was limited to subclinical seroconversion,⁹⁵⁵ and no HPAI H5N1 infections have been reported in horses to this point.

Past outbreaks of HPAI originated from one virus strain. However, antigenic drift and reassortment have resulted in a diversification of HPAI H5N1 viruses, both genetically and antigenically. Based on the HA sequence, ten clades (clade 0–9) are currently recognized, some of which are divided into second- and third-order clades.^{547,674,675} Recently, only viruses of clades 1, 2, and 7 have been isolated (http://www.who.int/influenza/gisrs_laboratory/201101_h5n1evoconceptualdiagram.pdf): clade 2.1 represents Indonesian H5N1 viruses, whereas Qinghai Lake H5N1 viruses^{279,281,1247} and their European, Middle Eastern, and African descendants form clade 2.2. Clade 2.3 viruses have become dominant in southern China, but have also been isolated in Hong Kong, Vietnam, Thailand, Laos, Malaysia, and Japan. Other Japanese H5N1 viruses belong to clade 2.5, which also includes viruses from Korea and China. Clade 2.4 is formed predominantly by chicken viruses from southern China (Yunnan and Guangxi Provinces). Human infections have been caused by viruses of clades 0, 1, 2.1, 2.2, 2.3, and 7. Viruses of clade 2.2 have spread to three continents and continue to infect humans. The evolution of these viruses has been studied intensively.^{281,451–454,1054,1409,1785,1948} The NA genes of HPAI H5N1 viruses can be divided into two lineages: one possesses a 19-amino-acid deletion in the stalk region (amino acids 54–72); the second comprises viruses with a full-length NA stalk or with a 20-amino-acid deletion spanning amino acids 49–68.

Since their first appearance, multiple genotypes have been isolated that are indicative of frequent reassortment with viruses of other genotypes or subtypes.^{278,449,677,678,1089,1205,1296,1491,2157} One genotype became dominant in 2002^{280,1129,1205}; its descendants continue to circulate in Indonesia and have spread westward into the Middle East. In southern China and other parts of Southeast Asia, however, this genotype was replaced by viruses of another genotype (the Fujian-like viruses).¹⁹⁰²

Reassortment between HPAI H5N1 and circulating human influenza viruses could create highly pathogenic viruses that transmit among humans. While such an event (which would likely result in a devastating pandemic) has not occurred yet, experimental studies have demonstrated a high propensity of HPAI H5N1 viruses for reassortment with A(H1N1) pdm09¹⁵⁴⁸ or with seasonal H3N2 viruses.^{284,905,1198,1301} While viruses possessing the HPAI HA and NA genes in combination with human H3N2 internal genes failed to transmit among ferrets,¹³⁰¹ other reassortants were more pathogenic than either parent virus.¹¹⁹⁸

HPAI H5N1 viruses have been extensively studied in primary human cells^{264,265–266,300,369,611,848,1180,1405,1410,1639,1780,2354,2368,2369} and in several animal models including mice, ferrets, guinea pigs, and nonhuman primates.^{76,186,279,292,319,515,1097,1106,1731,1825,2075} In alveolar epithelial cells^{264,266,2354} and macrophages,^{300,611,848,1180,1410,1639,1780,2368,2369} HPAI H5N1 viruses typically—but not always—elicit higher levels of proinflammatory cytokines than are observed upon infection with contemporary human viruses. Upregulated factors include IFN- β , IP-10, RANTES, and IL-6 in alveolar epithelial cells, and TNF- α , IFN- α and - β , IP-10, RANTES, MIP-1, and MCP-1 in macrophages. Many of these factors are also upregulated in the lungs of infected mice,^{232,318,339,1148,1239,1640,1784,2017,2106} ferrets,²¹⁶ and nonhuman primates.^{76,186,319} In these animal models, HPAI are highly pathogenic and cause diffuse alveolar damage with massive infiltration of immune cells and infection of pneumocytes. In nonhuman primates, HPAI H5N1 viruses are more pathogenic than the 1918 virus, or reassortants possessing 1918 virus genes (HA and NA, or HA, NA, and NS) in the background of a contemporary human virus.^{76,186,2075}

H5N2

Pennsylvania Outbreak. In April 1983, a low virulent H5N2 virus (A/chicken/Pennsylvania/1/83) emerged in chickens in Pennsylvania. By October, this virus had mutated into a highly pathogenic variant (A/chicken/Pennsylvania/1370/83) with a mortality rate of more than 80% in chickens. The virus was eventually eradicated by the slaughter of more than 17 million birds. The avirulent predecessor was unusual in that it had multiple basic amino acids at the HA cleavage site. The virulent strain differed from its predecessor by only a few nucleotides¹⁰⁰² including one that caused the loss of the HA glycosylation site,^{415,1002} thereby exposing the multibasic HA cleavage site to ubiquitous cellular proteases, furin, and PC6.¹⁰⁰²

Mexican Outbreak. In May 1994, a mildly pathogenic H5N2 virus was isolated from Mexican chickens (A/chicken/Mexico/26654-1374/94). This virus was not eradicated by mass slaughter because it had already spread widely. Stepwise accumulation of mutations over several months yielded moderately (A/chicken/Puebla/8624-602/94) and highly (A/chicken/Queretaro/14588-19/95) pathogenic strains with

a series of basic residues at the HA cleavage site.^{602,836,2011,2013} Vaccination was implemented in 1995 and by 2001, more than 1 billion doses of inactivated vaccine had been used. Between 1998 and 2001, 459 million doses of recombinant fowl pox-vector vaccine were also administered. Cases of HPAI have not occurred since 1996; however, low pathogenic H5N2 strains continue to circulate, as do genetically related viruses in the neighboring countries of Guatemala and El Salvador. In 2005, an H5N2 virus with low pathogenicity emerged in chickens in Japan. This virus is a descendant of the virus responsible for the Mexican outbreak and is closely related to a virus isolated from Guatemala. The origin of the Japanese strain remains unknown.

H7N1

In March 1999, an LPAI virus of the H7N1 subtype was isolated from a poultry farm in Italy.^{226,227,229} The virus was not eradicated and the infection spread, resulting, in December, in the emergence of a highly pathogenic isolate. More than 13 million birds were destroyed to control the outbreak. The reappearance of this LPAI in August 2000 was controlled by additional depopulation followed by a vaccination campaign from November 2000 to May 2002. The vaccine was based on inactivated H7N3 virus to allow differentiation of infected and vaccinated animals (DIVA).²³¹ Vaccination in combination with intensive monitoring led to the eradication of this H7N1 virus.

H7N3

An outbreak of HPAI H7N3 viruses occurred in poultry farms in Pakistan in 1995. This outbreak killed 3.2 million birds and was brought under control by vaccination.¹⁴⁶² In 2001, H7N3 viruses of both high and low pathogenicity were again identified, and despite further vaccination, HPAI H7N3 viruses reappeared in 2003 and 2004, causing the death of an estimated 10 million birds. Outbreaks of LPAI and HPAI H7N3 viruses also occurred in Chile in 2002¹⁷⁵⁰ and Canada in 2004,^{122,161,815,1613} leading to the slaughter of 2 million and 19 million birds, respectively. In Canada, two workers involved in the depopulation developed symptoms of influenza virus infection, including conjunctivitis, headache, and coryza.^{815,2111} H7N3 viruses isolated from these individuals had increased binding affinity for human-type receptors (as did other recent North American H7 viruses tested in this study).⁹⁹ Both the Chilean and 2004 Canadian isolates arose from LPAI viruses by recombination events that inserted 10 amino acids from the NP protein¹⁹⁸⁹ (Chilean virus) or 7 amino acids from the M1 protein^{161,815,1614} (Canadian virus) into the HA cleavage site.

Again in Canada, an HPAI H7N3 virus caused another outbreak in 2007 among roosters in a broiler hatching egg farm. After hundreds of roosters in one of the barns died, all animals on the premise (53,000) were culled.^{122,1613} The source of the outbreaks is not known, although serologic data indicate that a low pathogenic H7N3 had circulated in some birds on the premise prior to the outbreak. Phylogenetic analysis indicates that the HPAI H7N3 virus was similar to North American H7 viruses isolated from waterfowl.

H7N7

In 2003, an HPAI of the H7N7 subtype caused outbreaks in layer farms in The Netherlands, resulting in the death or culling of more than 30 million birds.¹⁹⁵⁵ Experimental infection of chickens confirmed the highly pathogenic phenotype of the virus.^{486,487,2141} The outbreak spread to Belgium and Germany

but was brought under control by mass slaughtering. In The Netherlands, the outbreak was associated with one fatal human case, a veterinarian who contracted the disease, and with conjunctivitis in 78 individuals who either directly handled affected poultry or had family members who did.^{546,1085} These data suggest human-to-human transmission, and experimental infection of cats demonstrated that the virus isolated from the fatal case caused alveolar damage with infection of type II pneumocytes and nonciliated bronchial cells, comparable to infection with an HPAI H5N1 virus.²¹⁴⁰ The virus isolated from the fatal case differed by 14 amino acids from a virus isolated from an individual with conjunctivitis; the acquisition of PB2-627K (a known determinant of pathogenicity in mammals; see Molecular Determinants of Host Range Restriction and Pathogenesis section) was critical for increased pathogenicity and tissue tropism.¹⁴⁴³ Depopulation of infected poultry and the treatment of at-risk individuals with NA inhibitors likely prevented further spread to or among humans.

Further outbreaks of H7N7 HPAI occurred in the United Kingdom in 2008 and in Spain in 2009. In the United Kingdom in 2008, mild disease was first noted in a laying flock of chickens, followed by the death of approximately 10,000 birds (http://www.oie.int/wahid-prod/public.php?page=weekly_report_index&admin=0). The remaining 15,000 chickens in the flock were culled. In Spain in 2009, an outbreak of H7N7 HPAI in a layer hen farm resulted in the death of approximately 30,000 birds, while the remaining 278,640 birds on the farm were culled (http://www.oie.int/wahis/public.php?page=single_report&pop=1&reportid=8521).⁸⁶¹

Despite the typically mild symptoms of human infection with H7 viruses, these viruses cause systemic infections in experimentally infected mice and ferrets without prior adaptation.^{100,405}

Low Pathogenic H9N2 Avian Influenza Viruses

LPAI viruses of the H9N2 subtype became panzootic in the mid-1980s among chickens, ducks, turkeys, pheasants, quail, and ostriches in Europe, Africa, North America, Asia, and the Middle East.^{14,15,61,224,1200,1636,1864} Since the mid-1990s, several sublineages have become established in Asia, represented by the prototype viruses A/chicken/Beijing/1/94, A/duck/Hong Kong/Y280/97, and A/quail/Hong Kong/G1/97.^{307,679,1206} These viruses appear to evolve rapidly through reassortment and antigenic drift.^{846,873,1034,1174,1182,2005,2277,2285,2358} A recent computational analysis of available H9N2 sequences revealed multiple different genotypes that likely originated from frequent reassortment with viruses of various subtypes.⁴³⁷

H9N2 viruses were detected in approximately 5% of birds in live poultry markets in Hong Kong in 1997. These viruses were not highly pathogenic but caused respiratory symptoms and decreased egg production. Between 2001 and 2003, H9N2 viruses were the most prevalent subtype in live poultry markets in Hong Kong, presenting in various different genotypes.³⁰⁷ Viruses of the A/quail/Hong Kong/G1/97 lineage share six internal genes with the H5N1 viruses isolated from humans in Hong Kong in 1997, and reassortants between H9N2 and H5N1 viruses have been described.^{771,873,2285,2358} On several occasions, H9N2 viruses of the A/duck/Hong Kong/Y280/97 lineage have been isolated from pigs in China,^{342,1624,2332} and seem to reassort frequently in these animals.²³³⁷ In an experimental study, multiple reassortants were generated between

avian H9N2 and A(H1N1)pdm09 viruses, some of which were more pathogenic in mice than the parental viruses,²⁰⁰⁶ as has been observed for reassortants between HPAI H5N1 and seasonal H3N2 viruses.¹¹⁹⁸

In animal experiments, H9N2 viruses replicate in chickens and mice without adaptation^{307,2277}; subsets of these viruses cause acute respiratory distress syndrome with high lethality in mice.^{307,412}

Some H9N2 viruses bind to Sia α 2,3Gal (preferentially recognized by most avian viruses) and also to Sia α 2,6Gal (preferentially recognized by human viruses).^{1335,2332} This is consistent with the finding that a virus possessing avian H9N2-derived HA and NA genes in the genetic background of a human H3N2 virus requires little adaptation for transmission among ferrets.¹⁹²⁶

Continued circulation of H9N2 viruses in poultry populations, combined with frequent reassortment, occasional transmission to pigs, and recognition of human-type receptors, emphasize the pandemic potential of the currently circulating H9N2 viruses.

Vaccines for Avian Influenza Viruses

The increasing number of outbreaks caused by HPAI H5 and H7 viruses, the fact that H5 and H9 viruses are now enzootic in poultry populations in parts of the world, and the increasing number of human infections with H5, H7, and H9 viruses have spurred the development of avian vaccines for these viruses, and the vaccination of poultry flocks. Most approved vaccines for H5, H7, and H9 viruses are based on inactivated whole-virus preparations, although some live recombinant vaccines based on Newcastle disease and fowl pox virus are in use (reviewed in^{230,277,432,559,1072,1763}; for an overview of currently available avian influenza vaccines, see <ftp://ftp.fao.org/docrep/fao/011/ai326e/ai326e00.pdf>).

Official vaccination programs against H5N1 viruses have been carried out in Hong Kong, Indonesia, China, Vietnam, Russia, India, Pakistan, Egypt, and Côte d'Ivoire, but failed to eradicate H5N1 viruses in some of these countries. Possible reasons include limited coverage of vaccination campaigns, failure to induce sterilizing immunity that may result in undetected virus spread and evolution, and limited cross-reactivity with viruses of different clades.

Influenza in Swine

Since the isolation of the first influenza virus from pigs in 1930 (A/swine/Iowa/15/30 [H1N1]),¹⁸⁶³ swine influenza has become enzootic and is a prevalent respiratory disease in these animals. Avian and human viruses of several subtypes (or reassortants thereof) have caused local outbreaks or become enzootic in pigs (Table 41.2). Until 2009, human influenza viruses contributed to the establishment of several new lineages in pigs (Table 41.2), whereas swine influenza viruses only infected humans occasionally, and without sustained human-to-human transmission (reviewed in¹⁴⁵⁹; see also^{78,1081,2055,2163}). This situation changed dramatically with the H1N1 pandemic in 2009, which originated from pigs.^{388,604,1903}

Collectively, the prominent role for pigs in the emergence of pandemic influenza viruses is supported by several findings: (1) pigs can be naturally (Table 41.2) or experimentally^{306,876,1021,1869,2180} infected with avian or human viruses; (2) swine influenza viruses can play a critical role in the emergence

of new pandemic viruses,^{388,556,604,1903} although most (reassortant) swine viruses cause self-limiting infections in humans (see previous discussion), which, however, can be fatal^{315,607,1042,1618,1758,1906,2235,2236}; (3) epithelial cells in pig trachea contain both human- and avian-type receptors (i.e., Sia α 2,6Gal- and Sia α 2,3Gal, respectively)⁸⁸⁰; (4) frequent reassortment (both intra- and intersubtypic) has been described for viruses isolated from pigs, suggesting repeated mixed infections of swine, avian, and/or human viruses; and (5) in nature, continued replication of an avian virus in pigs leads to variants that preferentially recognize human-type receptors.⁸⁸⁰ These observations support the “mixing vessel” hypothesis that pigs are simultaneously infected with avian and human influenza viruses, which allow for the generation of reassortants capable of causing pandemics.¹⁸¹⁰

In pigs, influenza virus infections cause high morbidity, but typically low mortality. Signs of infection include inactivity, nasal discharge, coughing, fever, labored breathing, weight loss, and conjunctivitis. Infections are limited to the respiratory tract with tracheobronchial lesions. During the Spanish influenza of 1918/1919,¹⁰⁷⁹ pigs presented with symptoms similar to those observed in humans.¹⁸⁶³ Phylogenetic analyses indicate that the 1918/1919 human and swine viruses were genetically similar and likely originated from a common ancestor.^{647,1717}

Influenza in Swine—North America

The descendants of the H1N1 1918/1919 isolates, now referred to as “classic swine viruses,” circulated in pig populations for more than 6 decades.^{181,1285,1532,1572,1841,2161} However, serologic studies in 1988 and 1989 also indicated a low prevalence of H3N2 viruses.²⁶⁰ In North America, this changed in 1997 and 1998, when H3N2 double human/swine reassortant and triple human/avian/swine reassortant viruses emerged²³⁷³ (Fig. 41.9). The double reassortant virus possessed human-like HA, NA, and PB1 genes, while the remaining genes were of classic swine virus origin. This virus did not establish a stable lineage but was soon replaced by human/avian/swine triple reassortant viruses that contain HA, NA, and PB1 polymerase genes of human virus origin; PB2 and PA polymerase genes of avian virus origin; and NP, matrix (M), and nonstructural (NS) genes of classic H1N1 swine virus origin.^{972,1570,2209,2373} These triple reassortants have spread widely throughout the swine population,^{972,1570,2209,2373} and have been linked to respiratory disease in pigs and abortion in pregnant sows. The major difference between the double and triple reassortant viruses was the presence of avian-origin PB2 and PA genes, suggesting that these genes may have contributed to the genetic stability of the novel reassortant virus; however, no mechanistic explanation is currently available. Although the biologic significance remains unknown, it is interesting that the HA and PB1 polymerase genes share the same origin, because this occurred with the 1957 and 1968 human pandemic viruses.¹⁰⁰¹ The triple reassortant H3N2 viruses evolved into four HA clades and continue to circulate in North American pig populations along with several reassortants that carry the same internal genes (PB2, PB1, PA, NP, M, NS), but different HA and NA genes (Table 41.2). These reassortants include several different H3N2 viruses possessing human-like HA genes^{1729,2208,2209}; an H1N1 virus possessing classic swine HA and NA genes²²⁰⁸ (cH1N1); an H1N2 virus possessing a classic swine HA gene (cH1N2)^{305,970,971}; an H1N2 virus possessing a human-like HA gene⁹⁶⁹ (huH1N2); and an H1N1 virus possessing human-like

FIGURE 41.9. Recent reassortment events among North American swine viruses. In 1998, triple reassortant viruses emerged in North American pig populations that contained PB2 and PA genes of avian origin; PB1, HA, and NA genes of human origin; and NP, M, and NS genes that originated from classical H1N1 swine viruses. Subsequent reassortment events resulted in triple reassortant H1N2 and H1N1 viruses. In addition, human/swine reassortants of different genotypes have been isolated from North American pigs since 1998. The eight viral RNA segments are arranged from left to right according to their lengths, starting with the longest segment (i.e., PB2, PB1, PA, HA, NP, NA, M, and NS).

HA and NA genes²¹⁶² (huH1N1). Hence, while the HA and NA genes have been replaced frequently with genes of human or swine origin (further supporting the role of pigs as “mixing vessels”), the constellation of the internal genes (now referred to as TRIG—triple reassortant internal genes) has been stable. Moreover, experimental co-infection of pigs with classic H1N1 and triple reassortant H3N2 viruses resulted in the selection of the TRIG cassette in most viruses characterized.¹²⁹¹ The reason for the biologic fitness of the TRIG cassette in pigs is not known. In 2009, the introduction of NA and M genes of Eurasian avian-like swine virus origin into a triple reassortant swine virus created the A(H1N1)pdm09 virus. In addition, a reassortant between triple reassortant and seasonal H1N1 viruses infected three individuals in Canada in 2009, but did not spread further.⁷⁸

Several other wholly avian or reassortant viruses have been isolated from pigs in North America, but did not establish new lineages; these include avian viruses of the H1N1,⁹⁷³ H3N3,⁹⁷³ and H4N6⁹⁶⁸ subtypes, and reassortant viruses of the H1N1 and H1N2,⁹⁶⁹ H3N2,²³⁷⁴ H2N3,¹²⁹² and H3N1^{1185,1290} subtypes. The H4N6 virus isolated from pigs in Canada possessed two amino acid changes,⁹⁶⁸ one of which confers binding to Sia α 2,6Gal.⁷⁹ The H2N3 virus isolated from pigs in the United States was transmitted among experimentally infected pigs and ferrets, and its HA amino acid sequence suggests the ability to recognize mammalian-type receptors.¹²⁹²

Influenza in Swine—Europe

In Europe, three virus subtypes—H1N1, H3N2, and H1N2—are currently circulating in pig populations.^{1121,2137} Influenza viruses were first isolated from European pigs in 1938 and 1940.^{141,1139} Classic swine H1N1 viruses were detected in pigs in Czechoslovakia in 1950.⁴³⁵ These viruses were reintroduced in 1976 into pigs in Italy (Table 41.2), probably by pigs imported from the United States.¹⁴⁷⁶ In 1979, a wholly avian

H1N1 virus, closely related to a duck virus, was introduced into European pigs¹⁶³⁰ and replaced the classic H1N1 viruses in the 1990s.^{237,1274,1809,1824} These so-called Eurasian avian-like swine H1N1 viruses still circulate in European pig populations. New antigenic variants of this lineage have caused multiple outbreaks throughout European pig populations.^{183,396,1319} In 2001 and 2006, reassortant swine H1N1 viruses were isolated in France that arose from the reassortment of Eurasian avian-like swine H1N1 viruses with reassortant human-like swine H1N2 viruses (see later discussion¹¹¹⁶).

Human H3N2 viruses were introduced into pig populations in the early 1970s, where they established a new lineage.^{741,1670,1787} Multiple introductions of human H3N2 viruses into pigs occurred,^{51,237,1319,1388,1583,2067} and these so-called human-like swine H3N2 viruses circulated over the next decade. In 1984, severe disease among Italian and French pigs was traced to a novel reassortant H3N2 strain that possessed human-like HA and NA genes, while the internal genes were derived from Eurasian avian-like H1N1 swine viruses.^{220,238,1736,2101} The novel virus (referred to as Eurasian reassortant human-like swine H3N2 virus, Table 41.2) soon became enzootic and replaced the human-like swine H3N2 viruses. Viruses of this lineage continue to circulate to this day. Also, Eurasian reassortant human-like H3N2 swine viruses were transmitted to two children in The Netherlands,³²¹ and to a child in Hong Kong.⁶⁶⁸

Since the mid-1990s, H1N2 viruses have been isolated frequently that contain an HA gene similar to a human H1N1 virus introduced into pigs in 1977 (human-like swine H1N1, Table 41.2), and the remaining genes from Eurasian reassortant human-like swine H3N2 viruses.¹⁸⁴ These so-called reassortant human-like swine H1N2 viruses spread throughout European pig populations and established a new lineage.^{182,184,656,1306,1319,1817,2138} Since their emergence, the reassortant human-like swine H1N2 viruses have reassorted with avian-like swine H1N1 viruses or reassortant human-like swine H3N2 viruses.^{1319,2353}

Influenza in Swine—Asia

Some of the viruses detected in European and North American pig populations have also been isolated from swine in Asia. In the early 1970s, human H3N2 viruses were isolated from pig populations in Asia^{1113,1868} (Table 41.2), where they continue to circulate.^{1624,2332,2333} From the late 1970s onwards, human H3N2 viruses have co-circulated with classic swine H1N1 viruses in pig populations in several Southeast Asian countries.^{40,948,1867,1871,2301} During this time, multiple introductions of human H3N2 virus into Asian pig populations must have occurred, since the human H3N2 viruses detected in pigs typically resembled human epidemic viruses circulating at the time.^{652,956,989,1403,1485,1705,1866,1871,1872} Influenza H1N2 viruses (cH1N2) that resulted from reassortment of classic H1N1 swine viruses and human H3N2 viruses were first isolated in Japan in 1978^{1487,1994} and have since spread in the Japanese swine population.^{39,885,1484,1486,1584,1778,2316} H1N2 viruses of the same and different genotypes also circulate in other parts of Asia, including Taiwan, China, and Korea.^{932,946,948,1689,2096} Eurasian avian-like H1N1 viruses were first detected in Asian pigs in 1993⁶⁸⁰ and may be enzootic in pig populations in parts of Asia.^{1245,2027} A recent study also demonstrated the circulation of double and triple reassortant H3N2 viruses in pigs in China.²³³³ These viruses possess human-like HA and NA genes in combination with avian-like internal genes (double reassortants), while the NP gene of the triple reassortant viruses is of swine virus origin.²³³³ The gene constellation of these viruses is thus different from that of the North American double and triple reassortant swine viruses.

In 1998, avian H9N2 viruses were first detected in swine in Hong Kong but did not establish a stable lineage.¹⁶²⁴ However, different H9N2 viruses may now be circulating in pigs in Asia.^{342,2282,2332,2337} (Table 41.2). Based on their HA sequences, some of the swine H9N2 viruses may bind to human-type receptors.²³³²

HPAI H5N1 viruses have been isolated from pigs in Asia on several occasions,^{306,1526,1846,2026} although the prevalence of HPAI H5N1 viruses in pigs appears to be low.³⁰⁶ Moreover, H9N2 viruses have been isolated from pigs that possess HPAI H5N1-like sequences, suggesting reassortment between H5N1 and H9N2 viruses.³⁴¹

In addition to the established lineages, human H1N1 viruses have been isolated occasionally from pigs in Japan⁹⁸⁸ and China.^{2335,2338} In Korea in 2006, a novel H3N1 virus was isolated from pigs¹⁸⁵⁰ that possessed an HA gene from a human-like H3N2 virus, an NA gene from a swine H1N1 virus, and internal genes from swine H1N2 viruses. The H3N1 virus likely circulated for some time, since it donated the PB2, PA, NP, and M segments to an H5N2 virus isolated from pigs in 2008.¹¹⁷⁶ Another H5N2 virus isolated in the same study was a wholly avian virus. In addition, numerous reassortant viruses have been isolated from pigs in Asia,^{2002,2027,2158,2283,2336} suggesting frequent reassortment between swine, avian, and human influenza viruses.

Interspecies Transmission

The first report of interspecies transmission involving pigs dates back to 1938, when Shope presented serologic evidence for the transmission of a human virus to pigs.¹⁸⁶² Further evidence for virus transmission between these two species came in 1976, when an H1N1 swine virus was isolated from a soldier

who had died of influenza at Fort Dix, New Jersey.^{607,642,819,1013} This virus was subsequently isolated from five other soldiers; serologic studies suggest that more than 500 personnel were infected.^{443,607,819} As stated earlier, more than 50 cases of human infection with swine influenza virus had occurred until 2009 (reviewed in^{78,1081,1459,2055,2163}), some of which resulted in fatal outcomes.^{315,607,1042,1618,1758,1906,2235,2236} Although the A(H1N1)pdm09 virus was not isolated from pigs prior to the 2009 pandemic, sequence and phylogenetic analyses strongly suggest that this virus originated from pigs.^{388,604,1903} Recently, A(H1N1)pdm09 viruses have been reintroduced into pigs in several countries (http://www.oie.int/wahis/public.php?page=weekly_report_index&admin=0),^{1615,1919,2158,2232} and have reassorted with swine viruses.^{1304,1949,2158} It remains to be seen if these viruses will establish novel virus lineages in pigs.

Several other reports indicate the sporadic transmission of swine viruses to avian species, or *vice versa*: classic swine H1N1^{1404,2259} or triple reassortant H3N2 viruses have been isolated from turkeys²³¹⁴; surveillance studies suggest infection of ducks with swine H1N1²⁰⁸ or H1N2 viruses¹⁵⁷¹; avian H3N2 viruses likely transmitted to pigs^{1022,2315}; and serologic evidence also suggests the infection of Chinese pigs with H4, H5, and H9 influenza viruses.¹⁵²⁹ Moreover, two equine H3N8 viruses were isolated from pigs in China.²⁰⁹⁸

Influenza in Horses

Two different subtypes of influenza A viruses are recognized in horses: H7N7, historically referred to as equine 1, and H3N8,²¹⁷² referred to as equine 2. Equine influenza is typically associated with fever, nasal discharge, dry hacking cough, loss of appetite, muscular soreness, and tracheobronchitis. The disease is usually more severe with equine 2 (i.e., H3N8) viruses and can include inflammation of the heart muscle. Secondary bacterial infections can be fatal.

The first equine influenza virus (A/equine/Prague/56 [H7N7]) was isolated in 1956 during a widespread pandemic of respiratory disease among horses in Eastern Europe. The last confirmed outbreak of this subtype occurred in 1979.²²¹³ Anecdotal reports of equine H7N7 outbreaks in Egypt⁸⁷⁵ and India,¹⁸⁸⁴ and the sporadic detection of H7-specific antibodies in reportedly unvaccinated horses, suggest that the viruses may have still circulated in small geographic pockets and/or in a subclinical form since their last isolation. In 1963, an equine influenza virus of the H3N8 subtype (A/equine/Miami/63 [H3N8]) was isolated in the United States²¹⁷² and caused a major epidemic. It was later found to have been introduced into North American horses via the importation of horses from Argentina. Another enzootic with an H3N8 virus occurred in China in 1989. This virus caused morbidity rates of up to 80% and mortality rates of up to 20%.⁷⁰² Based on sequence analysis, the virus was of avian origin and unrelated to the H3N8 virus already established in horse populations.^{699,2217} It remained confined to the Chinese horse population and was not isolated after the mid-1990s.⁷⁰⁰ Several studies suggested reassortment between H7N7 and H3N8 horse viruses while they were co-circulating,^{8,90,884,1450} and intrasubtypic reassortment among H3N8 horse viruses.¹⁴⁵⁰ Moreover, phylogenetic separation of the Eurasian and American lineages has been observed in the equine H3 HA proteins since 1987; within the American lineage, three clades (original strains, Florida clade 1, Florida clade 2) are currently recognized (reviewed in³⁷¹).

An H3N8 virus isolated from a horse did not replicate in ducks but caused disease in experimentally infected mice and ferrets.⁶⁹⁹ More importantly, an equine H3N8 horse virus transmitted to dogs in North America in 2004,³⁵⁹ and has been circulating in domestic dogs since then. Inactivated vaccines against the H7N7 and H3N8 subtypes are widely used; however, with H7N7 viruses seemingly extinct in horses, the H7N7 vaccine component is no longer critical. Studies suggested that immunity conferred by inactivated vaccines is short lived.¹⁴³⁷ Therefore, between 1978 and 1981, and again in 1989, widespread epidemics of H3N8 viruses occurred in Europe and North America, affecting both unvaccinated and vaccinated horses. Outbreaks of equine H3N8 continue to occur throughout the world, probably supported by the international transportation of vaccinated horses, in which virus replicates in a subclinical form. For example, international transportation of vaccinated horses likely led to the introduction of equine influenza into Australia in 2007.²¹⁵ A cold-adapted, temperature-sensitive, modified live equine influenza virus vaccine has been licensed for use in the United States. Although this vaccine is safe and efficacious, it does not provide sterilizing immunity.^{261,1284,2082,2328} In addition, a recombinant canarypox virus vaccine expressing H3 HA is now licensed in several countries.⁴⁷⁰

Influenza in Dogs and Cats

Two reports demonstrated the natural infection of dogs with human influenza viruses.^{269,1753} However, these viruses did not establish stable lineages in dogs, in line with surveillance studies that show low levels of seropositivity to influenza viruses in dogs.^{459,1195,1651}

In 2004, outbreaks of respiratory disease occurred in racing greyhounds in Florida.³⁵⁹ The causative agent was an influenza A virus (A/canine/Florida/43/04 [H3N8]) closely related to contemporary H3N8 equine viruses, suggesting interspecies transmission. The virus spread among greyhound populations, indicating that the equine influenza viruses replicated in and transmitted among greyhounds. Serologic studies indicate that the virus has spread to other breeds, although it has not spread widely within the general dog population. The canine H3N8 influenza virus appears to be largely confined to animal shelters in some large cities in the United States where the turnover of dogs and introduction of new susceptibles has allowed this apparently inefficiently spread virus to be maintained for the past 11 years.³⁵⁹ The H3N8 viruses circulating in horses and dogs in North America have become genetically distinguishable and no interspecies transmission from horses to dogs or back to horses has been reported.^{1734,2300} Infection of dogs with an equine H3N8 virus was also reported in Australia in 2007.¹⁰⁴⁶ A retrospective study suggested that an outbreak of respiratory disease in English foxhounds in the United Kingdom in 2002 was also caused by an equine H3N8 virus.³⁷⁰ In experimental studies, horses infected with the canine virus seroconverted but showed little signs of disease.^{2299,2300} The infection of dogs with equine influenza viruses may be facilitated by the presence on canine respiratory epithelium cells of Sia α 2,3Gal receptors, which are preferentially bound by equine influenza viruses.^{370,1449} Experimental infection of chickens, turkeys, and ducks with the canine virus did not cause infection.¹³⁶⁹

In 2007, three genetically similar avian H3N2 influenza viruses were isolated in Korea from domestic dogs with severe respiratory symptoms.¹⁹¹⁵ Experimental testing showed

that these viruses cause tracheobronchitis and bronchiolitis in dogs,^{947,1916} and are transmitted to contact animals.¹⁹¹⁶ Surveillance studies demonstrated that avian H3N2 viruses circulate at low but detectable levels in dog populations in Korea^{31,1169} and China.¹²⁰⁹

Recently, domestic cats and zoo tigers died after eating poultry infected with HPAI H5N1 viruses,^{28,500,1005} and probable virus transmission was reported among tigers.²⁰⁵⁸ Several other reports now also indicate the infection of dogs^{206,325,624,1923} and cats^{1064,1104,1105,1733,1922,2120} with HPAI H5N1 viruses. Cats and dogs can also be infected with HPAI H5N1 viruses in experimental settings.^{624,1105,1733}

Influenza in Seals and Whales

The most significant epizootic in seals occurred in 1979 and 1980, when approximately 20% of the harbor seal (*Phoca vitulina*) population of the northeast coast of the United States died of a severe respiratory infection with consolidation of the lungs typical of primary viral pneumonia.⁶¹³ Antigenic and genetic analyses^{1143,2219} revealed that the influenza virus isolated from the lungs and brains of dead animals (A/seal/Massachusetts/1/80 [H7N7]) was of avian origin. This virus replicated to high titers in ferrets, cats, and pigs,²²¹⁹ and caused conjunctivitis in humans.^{2216,2219} The death of an experimentally infected squirrel monkey¹⁴⁵⁴ and recovery of the virus from several of its organs demonstrated systemic spread of this virus. From June 1982 to March 1983, harbor seals along the New England coastline again died of viral pneumonia,⁸⁰⁴ which was caused by an avian H4N5 virus that was antigenically and genetically related to avian viruses and replicated in the intestinal tracts of ducks, a characteristic of avian influenza viruses. Serology and direct virus isolation revealed infection of seals with influenza A viruses of the H3N3²¹⁴ and H4N6 subtypes,²¹⁴ as well as influenza B virus.^{1550,1582} Further surveillance studies identified antibodies to influenza A^{375,391,1527,1549,1550,1981} and B viruses in several seal species.¹⁵⁵⁰

Influenza viruses of the H13N2 and H13N9 subtypes were isolated from the lungs and hilar nodes of a stranded pilot whale.⁸⁰³ It is not known whether the influenza virus infection caused or contributed to the stranding of this whale. In addition, H1N3 viruses have been isolated from lung and liver samples of whales from the South Pacific.¹²⁸⁸

Influenza in Mink

Mink are naturally susceptible to infection with human and avian influenza viruses.^{1063,1562} Avian influenza viruses of the H10N4 subtype killed mink in Sweden and spread to contact animals.^{118,494,1063} In 2006, respiratory problems were noticed among mink in mink ranches in Canada; subsequently, an influenza A virus was isolated from one animal with clinical signs. Further analysis identified the virus as a swine triple reassortant H3N2 virus.⁵⁷² Influenza viruses of human, swine, avian, and equine origin replicate in experimentally infected mink,^{118,494,495,1343} and transmission to cage mates has been observed for human and avian viruses,^{118,1343,1561,2292} as well as for equine and swine viruses.²²⁹²

Experimental Infections

Mice

Although mice are not naturally infected, they can be experimentally infected with influenza A or B viruses. Most human

influenza viruses cause indiscernible infection of the upper and lower respiratory tract and do not cause lethal disease without adaptation, although A(H1N1)pdm09 viruses are more pathogenic than other human viruses.^{101,890,1302} By contrast, most avian influenza viruses will replicate in respiratory organs (but not cause lethal infections) without prior adaptation (reviewed in¹⁵⁴²), most likely because of the presence of Sia α 2,3Gal receptors in murine respiratory tissues.^{856,1528} Notable exceptions include the recently isolated H5N1 viruses, which can cause lethal infections without prior adaptation.^{593,1269,2106} Most laboratory strains are susceptible to infection with influenza A viruses and have been used widely to study the pathogenesis of and the immune response to influenza viruses. Knock-out mice are useful tools for deciphering the molecular basis of virus–host interactions. However, most laboratory strains lack the Mx gene, which plays a role in the innate host defense,^{838,1941} and data obtained from laboratory strains may not therefore be strictly comparable to natural virus infections. Recent studies have identified appreciable differences in susceptibility between mouse strains.^{153,1938} The comparison of influenza virulence and pathogenicity in different mouse strains may lead to a better understanding of the contribution of host genetics to infections with influenza viruses.

Guinea Pigs

Influenza virus propagation in guinea pigs was first reported in 1938,²²⁶⁴ then in the 1970s.^{1648,2014} Recently, guinea pigs have been established as a transmission model for influenza viruses.^{1264–1266,1434,1830,2004} Human, swine, and avian influenza viruses can be isolated from the lungs and nasal turbinates of infected animals, suggesting efficient virus replication; however, signs of disease such as weight loss and increased temperature are largely missing,¹²⁶⁵ and no mortality was observed upon infection with HPAI H5N1 or pandemic 1918 virus.²¹³⁰ The nasal tract and trachea of guinea pigs possess both avian-type (Sia α 2,3Gal) and human-type (Sia α 2,6Gal) receptors, whereas the lungs contain predominately avian-type receptors.²⁰⁰⁴

Ferrets

Ferrets infected with influenza A or B viruses develop a febrile rhinitis. Upon infection with human influenza viruses, the lesions are usually confined to the nasal mucosa, but infection of the lower respiratory tract has been demonstrated. The pathologic changes of bronchitis and pneumonia resemble those seen in humans,¹⁹⁰⁴ which makes ferrets a valuable animal model to study various aspects of influenza virus infection. Unlike mice, ferrets can also be used to study the transmissibility of influenza viruses. The high susceptibility of ferrets to human influenza viruses may be due to the predominance of Sia α 2,6Gal receptors in their upper respiratory tract.¹¹⁸⁴

Nonhuman Primates

Influenza viruses infect various Old and New World primates, such as chimpanzees, gibbons, and baboons, as well as rhesus, squirrel, African green, and cynomolgus monkeys.¹⁴⁵⁸ Several species (e.g., gibbons, baboons) can be infected and develop illness.⁹³⁴ Illness has also been observed in other species (e.g., cynomolgus, rhesus) experimentally infected with influenza virus.⁶⁷¹ Several human viruses known to be virulent in humans also produce illness in squirrel monkeys,^{1455,1458} indicating that nonhuman primates may be a useful animal model for

the study of influenza virus infections. Nonhuman primates have been used to test the pathogenicity of (reassortant) 1918 viruses,^{76,186,319,1068} HPAI H5N1 viruses,^{76,186,279,292,319,1106,1731,2075} and A(H1N1)pdm09 virus.^{890,1772}

MOLECULAR DETERMINANTS OF HOST RANGE RESTRICTION AND PATHOGENESIS

Four influenza virus proteins—HA, PB2, NS1, and PB1-F2—are known determinants of host-range restriction and pathogenicity. Other viral proteins also participate in these events.

The HA Protein

The HA protein is responsible for virus attachment and the subsequent fusion of viral and cellular membranes. It is synthesized as a single polypeptide chain (HA0) that undergoes posttranslational cleavage by cellular proteases. This cleavage is essential for infectivity because it exposes the hydrophobic N-terminus of HA2, which mediates fusion between the viral envelope and the endosomal membrane.^{1060,1159,2241}

HA Cleavage

HA is a critical determinant of the pathogenicity of avian influenza viruses, with a clear link between HA cleavability and virulence.^{833,1059,1959,2227} The HA proteins of highly pathogenic H5 and H7 viruses contain multiple basic amino acids at the cleavage site (Table 41.3), which are recognized by ubiquitous proteases such as furin,¹⁹⁷³ PC6,⁸³⁵ mosaic serine protease large (MSPL)^{1025,1564} and transmembrane protease 13 (TMPRSS13).^{1025,1564} For this reason, these viruses can cause systemic infections in poultry. In cell culture, the HAs of these viruses do not need exogenous proteases to form plaques. In contrast, the HA proteins of avirulent avian and nonavian influenza A viruses, with the exception of H7N7 equine influenza viruses,⁹⁹⁸ contain a single arginine residue at the HA cleavage site^{154,155} and are cleaved in only a few organs. These viruses, therefore, produce localized infection of the respiratory and/or intestinal tract that is usually asymptomatic or mild. The tissue tropism of viruses is thus partly determined by the availability of host proteases to recognize and cleave the two types of amino acid sequences found at the HA cleavage site. The significance of HA cleavability for pathogenicity of avian influenza viruses is underscored by the finding that the acquisition of a highly cleavable HA can convert avirulent strains to virulent ones, as occurred in Pennsylvania in 1983 (H5N2),¹⁰⁰² in Mexico in 1994 (H5N2),⁶⁰² in Italy in 1999 (H7N1),⁶² in Chile in 2002 (H7N3),¹⁹⁸⁹ and in Canada in 2004 (H7N3)¹⁶¹⁴ (Table 41.3).

Two groups of proteases are responsible for HA cleavage. The first group recognizes a single arginine and cleaves all HAs. Members of this group include plasmin,¹¹⁶⁰ blood-clotting factor X-like proteases,⁶⁵⁴ tryptase Clara,¹⁰²⁶ mast-cell tryptase,²⁹³ ectopic anionic trypsin I,²⁰⁸¹ tryptase TC30,¹⁷⁸⁹ miniplasmin,¹⁰²⁴ HAT (human airway trypsin-like protease),¹⁵⁹ TMPRSS2 (transmembrane protease serine S1 member 2),¹⁵⁹ and bacterial proteases.^{1577,2043} *In ovo*, a protease similar to the blood-clotting factor Xa that is present in allantoic fluid cleaves HA, which explains why influenza viruses grow efficiently in eggs.⁶⁵⁴ Tryptase Clara is secreted from specialized respiratory

/, HA cleavage site.

^aHA cleavability is enhanced by a single amino acid substitution that abrogates glycosylation near the HA cleavage site.

^bFor H5N1 HPAI viruses, there are numerous cleavage site motifs; several examples are listed here.

epithelial cells in rats and mice¹⁰²⁶; mast-cell tryptase is found in mast cells,²⁹³ whereas ectopic anionic trypsin I is present in stromal cells in the peribronchiolar region.²⁰⁸¹ The tissue tropism of tryptase TC30 is currently unknown. The type II transmembrane serine proteases HAT and TMPRSS2 localize to human airways and support influenza virus replication in cell culture.^{125,158,159} Miniplasmin is a trypsin-type serine protease in the epithelial cells of the bronchia that cleaves HA downstream of the consensus motif Gln(Glu)-X-Arg.^{1024,1447} Cleavage of HA by plasmin can be augmented by the ability of the A/WSN/33 (H1N1) NA protein to sequester its protease precursor, plasminogen.⁶⁵¹ Bacterial proteases can also activate HA, either directly or indirectly by activating plasminogen, a property that may explain the development of pneumonia after mixed infections with viruses and bacteria.²⁰⁴³

The second group of proteases that cleaves HA proteins^{834,1973} comprises the ubiquitous intracellular subtilisin-related endoproteases furin and PC6.^{835,1973,2178} These enzymes are calcium dependent, have an acidic pH optimum, and are located in the Golgi and/or *trans*-Golgi network.^{1058,1061,2179} Recently, two other ubiquitous type II membrane serine proteases (mosaic serine protease large form, MSPL, and transmembrane protease 13, TMPRSS13) were identified that do

not require calcium for enzymatic activity,¹⁰²⁵ and support the replication of an HPAI H5N1 virus in cell culture.¹⁵⁶⁴ The cleavage efficiency of these ubiquitous proteases is determined by the sequence at the cleavage site and absence or presence of a nearby carbohydrate chain on the HA molecule.^{415,640,831,832,834,1002,1003,1025,1426,1556,1577,2003,2154,2177} The proposed sequence required for HA cleavage is Q-R/K-X-R/K-R (X, nonbasic amino acid) in the absence of a nearby carbohydrate chain. The presence of a nearby carbohydrate chain requires insertion of two additional residues, Q-X-X-R-X-R/K-R, or alteration of the conserved glutamine at position -5 or the proline at position -6, B(X)-X(B)-R/K-X-R/K-R (B, basic residue). The presence of direct repeats of basic amino acid insertions of various lengths in the HA proteins of several H5 and H7 viruses suggests that these sequences arose from polymerase stuttering,¹⁶³¹ likely caused by secondary structure in the template RNA. HA cleavage efficiency can also be affected by the nature of the amino acid immediately downstream of the cleavage site, that is, the N-terminal amino acid of HA2.⁸³²

Introduction of multibasic HA cleavage sites into low-pathogenic avian H6N1¹⁴⁴⁵ or H9N2⁶³⁹ viruses created highly pathogenic variants. However, this finding is not universally applicable, as the introduction of multibasic HA cleavage sites

into low-pathogenic H5N1¹⁴⁹ or H3N8 viruses,¹⁹⁵¹ or into a human H3N2¹⁸¹⁸ virus did not create highly pathogenic viruses. Thus, a multibasic HA cleavage site seems to be necessary, but not always sufficient for high pathogenicity.

Sialic Acid Receptors

Influenza viruses bind to sialic acids, that is, negatively charged 9-carbon sugars that typically occupy the terminal positions of glycoproteins or glycolipids. The term sialic acid is now usually used for the most common member of the group, *N*-acetylneuraminic acid (NeuAc). Another sialic acid species that is not synthesized in humans, *N*-glycolylneuraminic acid (NeuGc), is also recognized by some influenza viruses; in fact, influenza viruses differ in their recognition of these two sialic acid species.⁷⁹⁸ Most sialic acids are linked to galactose (Gal) or *N*-acetylgalactosamine (GalNAc) by α 2,3- or α 2,6-linkages (Sia α 2,3/6Gal, Sia α 2,3/6GalNAc), or to *N*-acetylglucosamine (GlcNAc) by α 2,6-linkages (Sia α 2,6GlcNAc).^{1795,2147}

Sialic Acid Receptors in Humans

Early studies demonstrated that epithelial cells in human trachea contain Sia α 2,6Gal sialyloligosaccharides on their cell surface but lack those with α 2,3-linkage.³⁴⁵ Consequently, viruses with Sia α 2,6Gal specificity (i.e., human virus isolates, which preferentially bind to Sia α 2,6Gal), but not those with Sia α 2,3Gal specificity (i.e., avian virus isolates, which preferentially bind to Sia α 2,3Gal), bind to the epithelial cells lining the human trachea.³⁴⁵ Recent data obtained with *in vitro* differentiated human epithelial cells from tracheal/bronchial tissues suggest a more complex situation: Nonciliated epithelial cells express Sia α 2,6Gal oligosaccharides and are predominantly infected by human virus isolates, whereas ciliated cells contain Sia α 2,3Gal oligosaccharides and are preferentially infected by avian virus isolates.¹³³⁶ Additional studies of human respiratory tissue have shown that while Sia α 2,6Gal oligosaccharides are dominant on epithelial cells in nasal mucosa, paranasal sinuses, pharynx, trachea, and bronchi, Sia α 2,3Gal oligosaccharides are found on nonciliated cuboidal bronchiolar cells at the junction between the respiratory bronchiole and alveolus, and on type II cells lining the alveolar wall^{85,1521,1854,2311} (Fig. 41.10).

Attachment and infection data for viruses of known receptor specificity are consistent with this distribution of Sia α 2,3Gal and Sia α 2,6Gal oligosaccharides.^{1854,2139} These findings offer an explanation for the severe pneumonia observed after infection of humans with some avian influenza viruses^{320,322,546,1993} and suggest that the limited human-to-human transmission of highly pathogenic avian H5N1 viruses likely reflects the restrictive replicative efficiency of these viruses in the upper portion of the respiratory tract, where transmission could occur via droplets generated by coughing and sneezing (Fig. 41.11). Conversion to preferential recognition of the human-type receptor thus is required for efficient human-to-human transmission, an assumption supported by the finding that the earliest isolates in the 1918, 1957, and 1968 pandemics preferentially recognized Sia α 2,6Gal, rather than Sia α 2,3Gal, sialyloligosaccharides.¹³³⁰ One study found higher amounts of Sia α 2,3Gal in the respiratory tract of children compared to adults,¹⁵²⁰ a finding that may suggest higher susceptibility of children to infection with avian influenza viruses. Another study reported predominant expression of Sia α 2,3Gal in epithelial cells of the human eye,¹⁵⁶⁷ which may explain the conjunctivitis associated with H7 influenza virus infections.

SIALIC ACID RECEPTORS IN OTHER MAMMALS

Epithelial cells in pig trachea contain both Sia α 2,3Gal and Sia α 2,6Gal,^{80,880,1478,1939,2136} which may explain why this species can be infected by both avian and human influenza viruses.¹⁰²¹ For mice, one study reported the expression of both types of receptors in the trachea, lung, and other organs,¹⁵²⁸ while another study did not detect human-type receptors in these animals.⁸⁵⁶ Ferrets express predominantly Sia α 2,6Gal on cells of the upper respiratory tract.^{85,1184} Equine viruses prefer Sia α 2,3Gal sialyloligosaccharides, which predominate in horse trachea.^{887,1449,2010} These studies also demonstrated that epithelial cells in horse trachea express NeuGc in addition to NeuAc, and that influenza viruses isolated from horses bind to oligosaccharides possessing NeuGc. Sia α 2,3Gal is also found on epithelial cells in the respiratory tract of dogs,^{370,1293,1449} and in the lungs of seals and whales.⁸⁸³ The nasal tract and trachea of guinea pigs possess avian-type (Sia α 2,3Gal) and human-type (Sia α 2,6Gal)

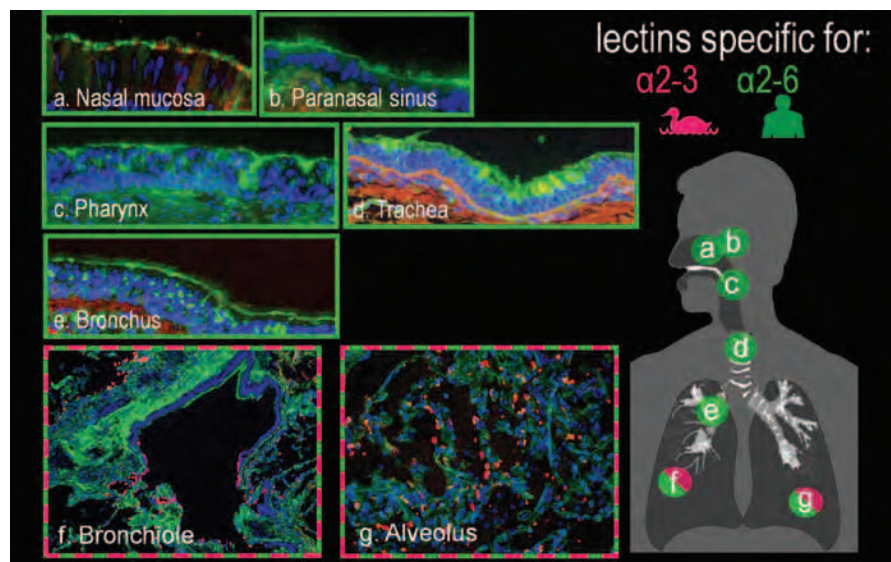

FIGURE 41.10. Expression of human virus (Sia α 2,6Gal) and avian virus (Sia α 2,3Gal) receptors in human respiratory tissue. The indicated tissues were tested with *Sambucus nigra* lectin (green), indicating the presence of sialic acid linked to galactose by an α 2,6-linkage (Sia α 2,6Gal), or with *Maackia amurensis* lectin (red), indicating the presence of Sia α 2,3Gal. Cells were counterstained with DAPI (4,6-diamidino-2-phenylindole; blue). In the nasal mucosa, paranasal sinuses, pharynx, trachea, and bronchus, Sia α 2,6Gal dominated. In the bronchiole and alveolus, both Sia α 2,6Gal and Sia α 2,3Gal were detected. (From Shinya K, Ebina M, Yamada S, et al. Avian flu: influenza virus receptors in the human airway. *Nature* 2006;440:435–436, with permission.)

FIGURE 41.11. Model for the emergence of avian-derived influenza A viruses capable of being transmitted efficiently among humans. Avian influenza viruses preferentially bind to Sia α 2,3Gal oligosaccharides and contain Glu at position 627 of their PB2 protein (see The Replication Complex section). After transmission to humans, these viruses can infect epithelial cells in the lower respiratory tract that contain Sia α 2,3Gal oligosaccharides on their surface. However, due to their limited replication in mammalian cells (determined by PB2-627E) and their restriction to the lower respiratory tract, viruses do not efficiently spread among humans. The current working model predicts at least two changes for the generation of avian-derived viruses that are efficiently transmitted among humans: **(A)** mutations (e.g., PB2-627E to PB2-627K) that increase the viruses' replicative ability in mammalian cells and also provide a growth advantage at the lower temperature in the upper respiratory tract, and **(B)** changes in HA that allow the virus to bind to Sia α 2,6Gal oligosaccharides that are prevalent on epithelial cells of the upper respiratory tract. These two changes are likely required but not sufficient for the generation of a pandemic H5N1 virus. Additional, yet unknown, mutations may be required for efficient transmission among humans.

receptors, whereas the lungs contain predominately avian-type receptors.²⁰⁰⁴

SIALIC ACID RECEPTORS IN AVIAN SPECIES

The epithelial cells of duck intestine (where avian influenza viruses replicate) express predominantly Sia α 2,3Gal,⁸⁸² although small amounts of Sia α 2,6Gal have been detected in the intestinal and respiratory tract.^{578,580,586,1041,1103,1654,2339}

The duck intestinal tract also possesses NeuGc, which appears to be absent in chickens.⁸⁸⁸ In the respiratory and intestinal tract of chickens, Sia α 2,6Gal and Sia α 2,3Gal are expressed.^{578,580,586,695,1036,1103,1654,2339} Similarly, both Sia α 2,3Gal and Sia α 2,6Gal are expressed on tracheal and intestinal cells of quail, turkey, pheasant, and guinea fowl,^{580,695,1041,1654,2186,2339} that is, species that may play a role in the adaptation of avian influenza viruses to mammalian species (see Role of Terrestrial Poultry in the Emergence of New Influenza Viruses section). However, differences exist among poultry species in the relative abundances of influenza virus receptors in the different organs and cell types tested.^{578,586,695,1036,1041,1103,1654,2339} Substantial amounts of Sia α 2,6Gal were detected in the respiratory tract of pigeons,¹²⁵⁰ which are not known to play a significant role in influenza virus ecology.

Receptor Specificity of Influenza Viruses

The specificity of HA for the different sialyloligosaccharides is responsible for the host-range restriction of influenza virus. Human and classical H1N1 swine influenza viruses bind preferentially to Sia α 2,6Gal, whereas most avian and equine viruses have higher binding affinity for Sia α 2,3Gal.^{343,589,882,1330,1333,1533,1743,1744,1746,1889,1969}

Receptor specificity is determined by the amino acids that form the receptor-binding pocket. For H2 and H3 HAs, glutamine at position 226 and glycine at position 228 (found in avian viruses) determine the specificity for Sia α 2,3Gal oligosaccharides, whereas leucine and serine at these positions (found in human viruses) confer Sia α 2,6Gal specificity in H2 and H3 viruses.^{343,1330,1463,1745,2034,2164} (Fig. 41.12). For H1 viruses, aspartate at positions 190 and 225 (found in human viruses) confers binding to α 2,6, while aspartate and glycine at these positions (found in swine viruses) allow binding to both α 2,6 and α 2,3 linkages; glutamate and glycine at positions 190 and 225 (found in avian viruses) are responsible for the interaction with α 2,3-linked sialic acids.^{590,1070,1330,1333,1716,1937,1969,1972,2034,2107}

In addition to these key residues, the amino acids at several other positions also affect receptor-binding

FIGURE 41.12. Structural models of HA–glycan receptor complexes. A: Interaction of avian H2 HA receptor-binding site (magenta) with avian-type receptor (green). **B:** Interaction of human H2 HA receptor-binding site (gray) with human-type receptor (orange). (From Viswanathan K, Koh X, Chandrasekaran A, et al. Determinants of glycan receptor specificity of H2N2 influenza A virus hemagglutinin. *PLoS One* 5:e13768, with permission.)

properties.^{1330,1333,1372,1380,1627,1743} X-ray crystallographic structures of HA proteins in complex with receptor analogs are available for human H1–H3 HAs,^{484,590,1246} avian H1–H3 and H5 HAs,^{590,708,709,1246} and swine H1 and H9 HAs,^{590,709} and provide detailed insights into the role of individual HA amino acids in receptor binding.

With the use of synthetic sialylglycopolymers,⁵⁸⁴ glycan arrays that allow the simultaneous testing of hundreds of carbohydrates and glycoproteins,¹⁹⁶⁹ and surface plasmon resonance assays,²⁰²⁹ a more complex picture of influenza viral receptor specificities has emerged. Binding of influenza viruses to their receptor is not only determined by the linkage between the sialic acid and the penultimate sugar residue (α 2,3 vs. α 2,6) but also by the nature of the penultimate sugar (Gal, GalNAc, or GlcNAc), the length of the carbohydrate chain, and the inner core of the carbohydrate (such as the linkage between the second and third sugar residue, modifications such as sulfation, or other sugar residues such as fucose).^{268,579–581,586–588,795,1112,1216,1332–1334,1768,1937,1969,1971,2306} Noteworthy differences exist between human and avian influenza viruses, and among avian viruses. For example, viruses

isolated from ducks, chickens, and gulls differ in their preference for the inner core structure of the receptor.⁵⁸¹ Avian influenza viruses favor NeuAc α 2,3 attached to shorter carbohydrate chains over the same sialic acid attached to a long chain; by contrast, seasonal human H1 and H3 influenza viruses bind to α 2,6 linkages preferentially in the context of long oligosaccharides^{795,1112,1969}; thus, avian virus HAs bind to their receptors in a narrow cone-like topology, whereas human virus HAs bind in a more flexible umbrella-like topology.^{268,1937} These differences in receptor-binding specificities can be correlated with specific differences in the HA sequence and/or structure.^{343,373,583,585,740,1330,1333,1533,1745,1968–1969,1970,2288}

Receptor Specificity of Avian Influenza Viruses

H5N1 viruses bind efficiently to Sia α 2,3Gal.^{579,1331} Mutations at position 190 or 225 that change the receptor-binding specificity of H1 HAs do not confer H5N1 virus binding to Sia α 2,6Gal; however, the introduction of human-type amino acids at positions 226 and 228 increases binding to Sia α 2,6Gal, while retaining substantial binding to Sia α 2,3Gal.^{746,1970}

H5N1 viruses isolated from infected individuals typically retain specificity for Sia α 2,3Gal.^{579,1331,1969,2297} However, several H5N1 viruses have been isolated that recognize Sia α 2,6Gal and Sia α 2,3Gal.^{48,579,1856,1968,2196,2297,2320} This change in binding properties can be linked to several specific amino acid changes in HA, most notably a serine-to-asparagine mutation at position 227, with or without a mutation at position 158 that results in the loss of a glycosylation site. Passage in ducks of a virus possessing asparagine at position 227 resulted in reversion to serine and reduced human-type receptor-binding specificity,¹⁸⁵⁷ suggesting that the human-adapting mutation is not stably maintained in ducks. One study tested all naturally or experimentally identified mutations that alter H5 receptor-binding specificity in the same genetic background and noted differences in their effect on binding to Sia α 2,6Gal.³¹⁴

Poultry H9N2 viruses isolated in China in 1999 possessed mutations at positions 190 and 226¹²²⁷ that conferred binding to Sia α 2,6Gal.^{1335,1776} These viruses, which also infected humans,^{1227,1626} demonstrated that variants with human-type receptor-binding properties can emerge in avian species. Similarly, several low pathogenic H7 viruses isolated from avian species and humans in the United States in 2002 to 2003 and in Canada in 2004 showed increased binding to Sia α 2,6Gal, although they retained their ability to bind to avian-type receptors.⁹⁹

Receptor Specificity of Human Influenza Viruses

The HA proteins of the pandemic 1918, 1957, and 1968 viruses originated from avian influenza viruses; nonetheless, the earliest available human isolates of these pandemic viruses already possessed Sia α 2,6Gal receptor-binding specificity,^{343,628,1330,1969} indicative of strong selective pressure. However, early pandemic H3N2 viruses differ from more recent isolates in their amino acid sequence and their binding affinity to nonciliated cells.^{1234,1329,1333,2061}

For the pandemic 1918 virus, two variants have been identified that differ at amino acids 190 and 225: A/South Carolina/1/18 (possessing aspartate at positions 190 and 225 as typically found in human influenza viruses) binds to Sia α 2,6Gal and transmits efficiently among ferrets, whereas A/New York/1/18 (possessing aspartate at position 190 but glycine at position 225) binds to both Sia α 2,6Gal and Sia α 2,3Gal and transmits with reduced efficiency compared to A/South Carolina/1/18.^{628,1937,1969,2107} Replacement of aspartate at positions 190 and 225 with the avian-like amino acids at these position—that is, glutamate and glycine—abolishes binding to Sia α 2,6Gal and transmission in ferrets.²¹⁰⁷ The X-ray crystallographic structure of a 1918 HA protein in complex with receptor analogs demonstrates how this overall avian-like protein interacts with human-type receptors.⁵⁹⁰

The A(H1N1)pdm09 viruses possess aspartate at positions 190 and 225 and bind efficiently to Sia α 2,6Gal,^{285,1302,2307} although one study reported dual recognition of both Sia α 2,6Gal and Sia α 2,3Gal.³⁰³ Molecular dynamics simulation of H1 proteins of the 1918 pandemic, a swine virus from 1930, a seasonal human H1N1 virus from 2005, and the A(H1N1)pdm09 virus showed that lysine at position 145 and glutamate at position 227 [found in the A(H1N1)pdm09 virus] increased the binding affinity to a human-type receptor, and that aspartate 225 increased the number of hydrogen-bonding interactions compared to glycine at this position.¹⁵⁴⁰ An aspartate-to-glycine

change at position 225 (H3 numbering; position 222 in H1 numbering) has been found in some A(H1N1)pdm09 viruses and appears to correlate with more severe disease outcomes in humans.^{34,282,448,637,863,1027,1168,1303,1389,1593,1671} Few transmission events have been reported for this variant,¹⁶⁸⁷ suggesting that it does not transmit efficiently among humans. The aspartate-to-glycine change at position 225 arises during passage in eggs or adaptation to mice and increases virulence *in vitro* and *in vivo*.^{868,1781,2286,2362} Experimental infection of pigs with a mixed population of viruses encoding glycine or glutamate at position 225 resulted in the selection of glutamate in viruses isolated from nasal secretions, but glycine in viruses isolated from the lower respiratory tract.¹⁷⁸

Glycan arrays in combination with X-ray crystallographic structures of pandemic 1957 H2 HAs highlight the significance of position 226 for H2 HA receptor-binding specificity.²²⁸⁸ This is further supported by the finding that A/El Salvador/2/57, possessing glutamine and glycine at positions 226 and 228, preferentially binds avian-type receptors and transmits poorly among ferrets, while A/Albany/6/58, possessing leucine and serine at position 226 and 228, recognizes human- and avian-type receptors and transmits efficiently in ferrets.¹⁶⁰⁹ Moreover, a mutational study demonstrated a critical role for the amino acids at positions 226 and 228 in converting an avian H2N2 virus into one that binds human-type receptors.²¹⁶⁶ The amino acids at position 137 and 193 also contributed to receptor-binding specificity.²¹⁶⁶

Glycosylation

Influenza virulence and host range are also affected by the number and location of oligosaccharide side chains, which are not conserved among strains or subtypes.^{859,1533} HAs typically contain 5 to 11 glycosylation sites that affect receptor-binding affinity and/or specificity,^{404,583,694,1216,1331,1555,2097,2189} antigenicity,^{3,52,379,1656,1777,2196,2200} innate immune responses,^{298,1709,2045} replication,^{59,2174} fusion activity,¹⁵⁵⁷ virulence,^{744,1342,1463,1632,1708,2156} and host range.¹⁷⁵² For efficient virus replication, a functional balance between HA and NA is critical.^{55,2175} Growth restrictions due to the lack of HA glycosylation site(s) can be partially overcome by amino acid substitutions in NA.^{55,2175}

Role of Terrestrial Poultry in the Emergence of New Influenza Viruses

Terrestrial poultry, such as chickens and quail, are susceptible to infection with influenza viruses. Most influenza viruses circulating in wild birds are typically asymptomatic in poultry, but their continued circulation among terrestrial poultry could lead to viruses with increased virulence in these birds.

Adaptation of waterfowl viruses in terrestrial poultry may lead to the emergence of viruses that are better able to replicate in humans or pigs than their original counterparts.^{580,695,1041,1654,2186,2339} due to altered receptor specificity.^{841,1331,1335,1925} Support for this hypothesis comes from the finding that viruses isolated from terrestrial poultry resemble human viruses in their low affinity for Sia α 2,3Gal compared to viruses isolated from wild birds¹³³¹ and that the receptor specificity of H9N2 viruses isolated from terrestrial poultry, but not that of viruses isolated from aquatic birds, is similar to the receptor specificity of human isolates.^{1335,1776} The H5N1 viruses isolated from terrestrial poultry are characterized by an additional glycosylation site in HA that reduces the affinity for the

receptor and, in some instances, by a deletion in the NA stalk that reduces NA functionality and balances the functions of these two proteins. The presence of additional glycosylation sites and a deletion in the NA stalk are typical for human viruses¹³³¹ and have also been found in different virus subtypes isolated from terrestrial poultry.^{55,62,116,145,146,221,622,1331,1355,1401,1776,1932} Collectively, these data suggest that waterfowl viruses acquire certain mutations in terrestrial poultry, such as NA stalk deletions and additional HA glycosylation sites that may facilitate their transmission to humans or other mammals such as pigs.

Host Cell-Mediated Selection of Antigenic Variants

In 1942, Burnet and Clarke²⁰³ first described “O” (original) and “D” (derived) variants that differed in their ability to agglutinate human or guinea pig erythrocytes after passage in eggs. Subsequent studies established that the antigenicity of influenza A and B viruses grown in embryonated chicken eggs differs from that of viruses propagated in cell culture, including chicken embryo fibroblasts.^{583,991,993,1335,1738,1800} For minor populations of egg isolates, however, the antigenic properties remained identical to those of cell culture isolates.¹⁵⁸⁹ The HA sequences of cell culture–grown but not egg-grown viruses are identical to those of the original isolates, demonstrating that HA variants arise during virus replication in eggs.^{202,296,582,583,585,589,605,992,1277,1278,1699,1739,1800,1971,2028} Moreover, human isolates tend to grow better in cell culture than in eggs,^{458,1415} further suggesting that human viruses undergo selection in eggs. Historically, human viruses were isolated by inoculation of samples into the amniotic cavity of embryonated eggs, followed by virus amplification in the allantoic cavity. Some recent human viruses do not grow in eggs when inoculated into the allantoic cavity. Mutations in the HA of egg-grown viruses cluster around the receptor-binding pocket, likely reflecting an adaptation to selective pressure in eggs. This selective pressure can be attributed to the fact that in addition to Sia α 2,3 sialyloligosaccharides, Sia α 2,6 sialyloligosaccharides exist on amniotic cells, whereas only Sia α 2,3 sialyloligosaccharides are found on allantoic cells.⁸⁸⁹

Currently, influenza vaccine viruses are propagated in embryonated chicken eggs. In animal models, however, vaccines prepared from cell culture–grown viruses induce better protective immunity than those grown in eggs,^{26,993,994,1394,1508,2261} a finding that was substantiated when these vaccines were tested in humans.^{27,1508} Influenza vaccine production in cell culture rather than eggs thus may be preferable.

The NS1 Protein

The NS1 protein functions as an IFN antagonist that allows efficient virus replication in IFN-competent hosts,^{599–600,601,1406,1978} in addition to roles in the splicing and nuclear export of viral mRNAs^{22,513,596} and the enhancement of viral mRNA translation.^{401,490} NS1 targets the production of type I IFN (IFN- α , IFN- β), and interferes with IFN-induced antiviral factors. These functions are described in the Innate Immune Responses section.

The Replication Complex

The influenza viral replication complex comprises the three polymerase proteins—PB2, PB1, and PA—and the nucleoprotein NP. The PB2 protein recognizes and binds to type I cap structures of cellular mRNAs. It has emerged as an impor-

tant determinant of virulence and host-range restriction. Early studies suggested that the PB2 segment,^{21,327,1991} in particular the amino acid at position 627,¹⁹⁹¹ was involved in host-range restriction.^{21,327,1991} The significance of this finding in the context of interspecies transmission was not recognized, however, until 2001, when a substitution at position 627 of PB2 from glutamic acid (found in most avian isolates) to lysine (found in all contemporary human isolates) was shown to enhance the pathogenicity of an HPAI H5N1 virus in mice.⁷⁵³

Multiple lines of evidence now suggest that PB2-627K is a major determinant of pathogenicity in mammals: (1) PB2-627K leads to increased virulence of HPAI H5N1 viruses^{593,753,1037,1783,1855}; (2) PB2-627K is selected during virus replication in humans¹¹⁶⁵; (3) PB2-627K was critical for the pathogenicity of an H7N7 virus isolated from a fatal infection in The Netherlands in 2003^{406,546,1443}; by contrast, viruses isolated from nonfatal cases and chickens contained glutamic acid; (4) HPAI H5N1 viruses with PB2-627K have been isolated from tigers (A/tiger/Suphanburi/Thailand/Ti-1/04 [H5N1])²⁸ and a cat in Thailand in 2004 (A/cat/Thailand/KU-02/04 [H5N1]); (5) viruses possessing PB2-627K were isolated after adaptation of H5N1, H7N7, and H9N2 viruses to mice,^{841,1203,1322,1860,2278} and after virus replication in pigs¹³¹²; (6) PB2-627K increases virus transmission in the guinea pig model¹⁹⁵²; (7) PB2-627K is selected during HPAI H5N1 virus replication in ostrich cells and ostriches¹⁸⁵⁸ and has been found in viruses isolated from turkeys, ostriches, emu, rhea, and quail, suggesting that PB2-627K selection can occur in some avian species, which may facilitate the adaptation of avian influenza viruses to mammals (see Role of Terrestrial Poultry in the Emergence of New Influenza Viruses section); and (8) PB2-627K increases replicative ability in mammalian cells,^{363,1324,1464,1855} particularly at the lower temperatures of the upper respiratory tract⁷⁵⁴ (Fig. 41.11). Collectively, these findings suggest that PB2-627K provides a replicative advantage in mammals and is hence selected in these species. However, PB2-627K also emerged in HPAI H5N1 viruses isolated from wild waterfowl at Qinghai Lake in 2005 (see The H5N1 Outbreak section)^{279,281,1247} and is maintained in descendants of the Qinghai Lake viruses to this day.

Considering the significance of PB2-627K for influenza virus replication in humans, the finding of PB2-627E (i.e., the avian-type amino acid) in A(H1N1)pdm09 viruses was unexpected. Two studies demonstrated that the lack of PB2-627K is compensated for by a basic amino acid at position 591.^{1373,2296} In fact, PB2-627K does not provide a replicative advantage in the background of A(H1N1)pdm09 viruses.^{785,907,2296,2377} Structural analyses demonstrated that positions 591 and 627 are in close proximity,^{1120,2041} and that a basic amino acid at position 591 alters both the shape and charges on the surface of the protein,²²⁹⁶ which may affect the interaction of PB2 with other host and/or viral factors.^{543,1374,1407} For example, one study suggested that the amino acid at PB2-627 affects the association of the polymerase complex with NP.^{1125,1701}

A second amino acid in PB2—at position 701—was first identified as a virulence factor of HPAI H5N1 viruses in mice,¹²¹² and is now known to facilitate viral adaptation to mammalian species. Replacement of aspartic acid (found in most avian influenza viruses) with asparagine at residue 701 enhances binding of PB2 to the cellular nuclear import factor importin α and facilitates PB2 nuclear import and replicative

ability in mammalian cells.^{566,568,569} This amino acid change was found upon adaptation of an avian H7N7 virus to mice⁵⁶⁷; it also proved to be critical for virus transmission in guinea pigs.^{595,1952} In addition, mouse-adapted human H3N2 viruses possessed the PB2-D701N mutation.¹⁶⁵⁵ Like PB2-627K, PB2-701N is selected during HPAI H5N1 virus replication in humans¹¹⁶⁵ and ostriches,¹⁸⁵⁸ but does not provide a replicative advantage to A(H1N1)pdm09 viruses.^{785,2296}

Replacement of the avian-type threonine residue at position 271 of PB2 with alanine (i.e., the residue typically found in human influenza viruses) increases virus replication in mammalian cells and mice.²⁰⁵ The PB2 protein of the A(H1N1)pdm09 virus (which is of avian-virus origin) encodes alanine at position 271, suggestive of human adaptation.

The PB1 protein possesses conserved motifs found in all RNA-dependent RNA polymerases¹³⁷ and is considered critical for the polymerase enzymatic function. In a minireplicon system, reporter gene expression was more efficient with avian than with human virus PB1 protein.¹⁴⁶⁴ Avian virus PB1 protein may hence provide a replicative advantage over its human counterpart, an attractive hypothesis since both the 1957 and 1968 pandemic strains contained avian PB1 genes (in combination with avian HA, or HA and NA genes^{1001,1813}). Moreover, in reassortment studies between HPAI H5N1 and human H3N2 viruses, one of the most pathogenic reassortants possessed the avian PB1 gene.²⁸⁴ Reassortment studies also demonstrated a critical role for the pandemic 1918 PB1 gene in virulence in animal models.^{1607,2206}

The PA protein is an integral part of the influenza viral replication complex with a role in the cap-snatching process.⁴¹⁸ Recent studies now also suggest a role for PA in the virulence of the A(H1N1)pdm09 virus^{1781,1921,2006} and in the adaptation of an avian H5N2 virus to mice.¹⁹²⁰

In addition to the polymerase genes, the NP gene may play a role in host range restriction.^{592,1810,1811,2066}

A large body of information demonstrates that the composition of the replication complex affects viral pathogenicity.^{284,905,1192,1198,1199,1300,1464,1548,1607,1819,2006,2019,2203,2206} As a general trend, more efficient replication in minireplicon assays translates into increased pathogenicity in animal models.

The PB1-F2 Protein

PB1-F2 is a short protein of 87 to 90 amino acids that was discovered in 2001.²⁹¹ It is expressed from the +1 reading frame of the PB1 gene of most avian and human influenza viruses; however, human H1N1 viruses isolated after 1950 encode a truncated version of 57 amino acids.^{291,2352} Most swine virus isolates (particularly classical H1N1 swine influenza viruses) do not encode a functional PB1-F2 peptide, due to several in-frame stop codons. These stop codons are also found in the reading frames of A(H1N1)pdm09 virus PB1-F2s, which likely originated from pigs; therefore, human pandemic viruses do not encode a functional PB1-F2 protein. Reconstitution of full-length PB1-F2 expression in the background of A(H1N1)pdm09 viruses had only minor effects on replicative ability and virulence in mice and ferrets,^{273,711,1592} suggesting that PB1-F2 is not critical for the pathogenicity of A(H1N1)pdm09 viruses. Phosphorylation of PB1-F2 may be critical for its function.¹⁴⁰² The role of PB1-F2 in viral pathogenicity is discussed in more detail in the Innate Immune Responses section.

The NA Protein

The sialidase activity of the NA protein removes sialic acid from sialyloligosaccharides, thereby serving two functions: (1) the removal of sialic acid from HA, NA, and the cell surface, facilitating virus release; and (2) the removal of sialic acid from the mucin layer, which likely allows the virus to reach the surface of the epithelial cells.^{1331,1602} The NA protein may also have a role in host-range restriction⁸⁰⁸ and pathogenicity.^{651,1607,1819} Notably, the NA activity of some avian viruses is more resistant to the low pH of the upper digestive tract than that of human- or swine-derived NA,^{2009,2025} a feature that may contribute to host-range restriction. Interestingly, low-pH stability has also been reported for the NA protein of the pandemic 1918 virus.²⁰²⁴ The NA protein of A/WSN/33 (H1N1) virus is critical for plaque formation in Madin-Darby bovine kidney cells and for neurovirulence^{1473,1821,1996}; these two phenotypes are linked to the loss of a carbohydrate chain on NA and the presence of a C-terminal lysine residue.¹²⁰⁸ The lack of the carbohydrate chain at position 146 of NA (N2 numbering) allows the NA protein to bind to and sequester plasminogen, a plasmin precursor. This function facilitates HA cleavage and, thereby, virus pathogenicity in mice.^{651,653,1208}

Multiple studies now indicate that the length of the NA stalk affects virulence and pathogenicity^{55,62,116,145,146,221,622,1331,1335,1342,1401,1439,1776,1869,1932,1988,2367}; deletions in the NA stalk have been observed after virus replication in eggs and in poultry, and among recent HPAI H5N1 viruses.

Like HA, the NA protein shows preference for certain types of sialyloligosaccharides according to the host species. Avian virus NAs cleave $\alpha 2,3$ -linked, but not $\alpha 2,6$ -linked, sialic acids. After their introduction into the human population, N2 NAs acquired the ability to cleave $\alpha 2,6$ -linked sialic acids in addition to $\alpha 2,3$ -linked sialic acids⁸⁴; however, the enzymatic activity for $\alpha 2,6$ -linked sialic acids is significantly lower than that for $\alpha 2,3$ -linked sialic acids. This acquired ability likely represents adaptation to the respective recognition pattern of the HA protein. NA substrate specificity is determined by the amino acid at position 275.¹⁰⁶⁹

CLINICAL FEATURES AND PATHOGENESIS IN HUMANS

Pattern of Virus Shedding

Human influenza viruses replicate almost exclusively in superficial cells of the respiratory tract. Influenza virus is released from the apical surface of the cell, which may limit more systemic spread but facilitate accumulation of virus in the lumen of the respiratory tract for transmission to the next susceptible host. Alveolar macrophages and dendritic cells can also be infected. Their role is in initiating the innate and cognate immune response to influenza virus by processing antigens and presenting them for recognition (see Innate Immune Cells and Cellular Immunity sections). Influenza virus replicates throughout the respiratory tract, with virus being recoverable from the upper and lower tracts of people naturally or experimentally infected with virus. The site of optimal growth in the respiratory tract for influenza viruses is, in part, determined by the prevalence of the Sia α -2,3Gal or Sia α -2,6Gal receptors (see the HA Protein section).

FIGURE 41.13. Six seronegative volunteers received $10^{4.0}$ TCID₅₀ of wild-type A/Bethesda/1015/68 virus intranasally on day 0.

The pattern of virus replication in six adult volunteers administered an influenza A/Hong Kong/68-like H3N2 virus, in relation to the onset of clinical symptoms, IFN response, and serum and nasal wash antibody responses, is presented in Figure 41.13.¹⁷²⁸ More recent work has defined the patterns of local and systemic chemokine and cytokine responses seen with experimental influenza infection.⁷⁶⁴

Virus replication peaks about 48 hours after inoculation and declines slowly thereafter, with little shedding after days 6 to 8. Peak virus titers in symptomatic adult volunteers range from $10^{3.0}$ to $10^{7.0}$ TCID₅₀/mL of nasopharyngeal wash. There was a positive correlation between the amount of virus shed and the severity of the clinical illness. Individuals who shed less than $10^{3.0}$ TCID₅₀/mL were either asymptomatic or had only minor upper respiratory tract symptoms. Even after infectious virus can no longer be recovered, viral antigen can be detected for several days in cells and secretions of infected individuals.^{119,467,2046} Viral antigen is detectable in conjunctival cells and secretions.²⁰⁴⁶ In children, virus can be found for up to 13 days after the onset of symptoms.⁵⁵⁵ The higher titers and more prolonged shedding in children contribute to the important role of this population in the spread of influenza.

The duration of shedding of A(H1N1)pdm09 virus is similar to that of seasonal influenza viruses. In immunocompetent patients, the A(H1N1)pdm09 virus is typically shed from the day prior to the onset of symptoms to 5 to 7 days after the onset of illness.^{131,2070,2334} The highest amounts of virus are shed within the first two days of illness. In a study of elementary school children (median age, 8 years), A(H1N1)pdm09 virus was isolated for a median 2 days after fever resolution.¹³¹ Early oseltamivir treatment within 48 hours of symptom onset significantly reduced the duration of shedding.^{1237,2334} More prolonged shedding of A(H1N1)pdm09 virus can occur in young children,¹²⁰¹ immunocompromised individuals,¹¹⁴⁵ and in patients with severe disease such as acute respiratory distress syndrome or fatal infection.²⁰⁷⁰

Pathology

Influenza A virus induces changes throughout the respiratory tract, but the most clinically important pathology develops in the lower respiratory tract.^{688,791–792,793,2183} During bronchoscopy in uncomplicated influenza infections, acute diffuse inflammation of the larynx, trachea, and bronchi are observed with mucosal inflammation and edema. Light microscopic studies of infected cells show that columnar ciliated cells become vacuolated, edematous, and lose cilia before desquamating down to a one-cell-thick basal layer. Submucosal edema and hyperemia occur with the infiltration of neutrophils and mononuclear cells.¹³²⁰ In more severe primary viral pneumonia, there is an interstitial pneumonitis with marked hyperemia and broadening of the alveolar walls, with a predominantly mononuclear leukocyte infiltration and capillary dilation and thrombosis. Influenza virus-specific antigen is present in types 1 and 2 alveolar epithelial cells, as well as in intra-alveolar macrophages^{685,1847} (Fig. 41.4). The pathologic changes associated with HPAI H5N1 viruses include a hemophagocytic syndrome, renal tubular necrosis, lymphoid depletion, and diffuse alveolar damage with interstitial fibrosis.^{267,310,1087,1101,1625,1993,2069,2116} Similarly, infection with A(H1N1)pdm09 virus leads to diffuse alveolar damage, hemorrhagic interstitial pneumonitis, and peribronchiolar and perivascular lymphocytic infiltrates^{86,625,684,705,706,1635,1927} (see The H5N1 Outbreak section).

Necrotizing changes may occur with rupture of alveoli and bronchiole walls. Influenza virus has been obtained from lungs at autopsy in titers of $10^{2.0}$ to $10^{5.7}$ 50% egg infectious doses per gram of tissue.¹²⁶²

At the cellular level, influenza virus shuts off cell protein synthesis and induces apoptosis as an additional mechanism of cell destruction.^{806,1130,1267,1424,1822,2355,2356} From the third to fifth day after onset of illness, mitoses appear in the basal cell layer, and regeneration of the epithelium begins. During this time, reparative and destructive processes may be present simultaneously. Complete healing of the epithelial damage takes up to 1 month.

Clinical Features

Adults

Infection with influenza A viruses results in clinical responses ranging from asymptomatic infection to primary viral pneumonia that rapidly progresses to a fatal outcome. The typical uncomplicated influenza syndrome is a tracheobronchitis with some involvement of small airways.^{200,441} The incubation period ranges from 1 to 5 days (reviewed in⁴⁶⁸). The onset of illness is usually abrupt, with headache, chills, and dry cough, which are rapidly followed by high fever, myalgias, malaise, and anorexia. Substernal tightness and soreness can accompany the cough. The most prominent sign of infection is fever that often peaks within 24 hours at 38°C to 40°C. The fever begins to decline on the second or third day of illness and has usually abated by the sixth day.⁴⁴¹ The elderly can have high fever, lassitude, and confusion without respiratory signs.

Physical findings in influenza are confined to the respiratory tract. Nasal obstruction, rhinorrhea, sneezing, and pharyngeal inflammation without exudate are common. Conjunctival inflammation and excessive tearing may occur. Conjunctivitis was the hallmark of an H7N7 outbreak in poultry workers in the Netherlands.⁵⁴⁶ Small cervical nodes can be felt in a minority of cases. Chest radiograph and auscultatory findings are usually normal, although occasionally patchy rales and rhonchi are heard.

As the fever declines, the respiratory signs and symptoms may become more prominent. The cough frequently changes from dry and hacking to one that produces small amounts of mucoid or purulent sputum. After the fever and upper respiratory tract symptoms resolve, cough and weakness can persist for 1 to 2 additional weeks. Illness is more frequent and more severe in cigarette smokers.⁹⁷⁴ The loss of the mucociliary blanket is a factor in a predisposition to secondary sinusitis and bacterial pneumonia. Although airflow in large airways is usually unaltered in uncomplicated influenza, there is an increase in bronchial reactivity to chemical and particulate stimuli during infection.²¹¹⁷ Small peripheral airways are often affected even in otherwise uncomplicated influenza A virus infections.⁷²¹ This small airway abnormality can persist after symptomatic illness has subsided. Alterations in pulmonary gas exchange are seen, with a depression of the diffusing capacity of carbon dioxide and an increase in the alveolar-arterial oxygen tension gradient.⁸³⁹ Tracheobronchial clearance of radiolabeled particles is depressed during acute influenza virus infections but returns to normal levels about 1 month later.²¹⁷ Although significant abnormalities in large and small airways can be demonstrated during acute infection and early convalescence, uncomplicated influenza appears to cause little permanent damage in the lung, even in patients with chronic obstructive lung disease.^{336,1167}

Clinical symptoms of A(H1N1)pdm09 virus infections in adults were similar to those of seasonal influenza, although gastrointestinal manifestations—including vomiting and diarrhea—occurred at higher rates (approximately 20–30%)^{86,1261} (see The H1N1 Pandemic in 2009 section). In addition, adults with A(H1N1)pdm09 infection were more likely to have radiographically confirmed pneumonia (4.0%) compared with those with seasonal H1N1 (2.3%) or H3N2 (1.1%) infection.⁹⁷

Children

The clinical manifestations of influenza in children are similar to those in adults, but there are some distinct differences. There is a proportionally greater burden of illness in children than in adults.¹⁶⁶⁸ Children have higher fevers that may be accompanied by febrile convulsions.¹⁶⁷⁸ At least 14% of fevers with respiratory tract symptoms that result in a pediatrician visit are caused by influenza viruses.^{629,633,635,2268,2271}

Otitis media, croup, pneumonia, and myositis are more frequent in children than in adults.^{782,1035} Otitis media develops in approximately 12% of influenza-infected seronegative children.²²⁷² Between 24% and 33% of children hospitalized with influenza A virus infection have otitis media.¹⁵⁹⁵ Although less well documented in children than in adults, bacterial sinusitis may follow acute influenza.

Studies in children have shown that some influenza A viruses are important causes of laryngotracheobronchitis (croup).¹⁰³⁵ Croup occurs predominantly in children younger than 1 year. Influenza-associated croup can be especially severe and occasionally requires intubation of the patient.¹⁹³ In a prospective study of 121 susceptible (seronegative) young children seen during an H3N2 virus outbreak, 5 of 60 infected infants had clinical and radiographic evidence of pneumonia.²²⁷⁰ Influenza A virus infection has been shown to exacerbate asthma.^{1083,1395} Children (especially those younger than 3 years) have a higher incidence of gastrointestinal manifestations such as vomiting and abdominal pain. Infection of neonates can present as unexplained fever¹³⁷⁵ and can be life threatening.^{81,1375} With HPAI H5N1 infections, acute respiratory distress syndrome is observed frequently (see The H5N1 Outbreak section).⁹⁵ Influenza A and B viruses are significant causes of serious lower respiratory tract disease that often lead to hospitalization of children^{398,634,1238,1503,1581,2062} and rarely to death.^{130,353}

Lower Respiratory Tract Complications

Three distinct syndromes of severe pneumonia can follow influenza infection in children or adults. Complications are most common in the elderly.¹²⁷⁹

Primary Viral Pneumonia

Primary influenza virus pneumonia was first described in fatal cases caused by the 1957 Asian influenza A virus (H2N2),^{1297,1320} although retrospectively, it occurred during previous influenza A epidemics.⁶⁴⁵ Primary viral pneumonia occurs predominantly in individuals at high risk for the complications of influenza virus infection (i.e., the elderly or patients with cardiopulmonary disease), but 25% of cases are in individuals without risk factors and an additional 13% are in pregnant women. The typical case of primary viral pneumonia develops abruptly after the onset of influenza illness. It progresses within 6 to 24 hours to a severe pneumonia with rapid respiration rate (30 to 60 respirations per minute), tachycardia (greater than 120 beats/min), cyanosis (in 80% of patients), high fever (average of 39°C), and hypotension. The illness may progress rapidly to hypoxemia and death in 1 to 4 days; the presence of frothy hemoptysis, tachypnea, and cyanosis portends a fatal outcome. Auscultatory findings include bilateral crepitant inspiratory rales. Examination by radiograph reveals mottled densities in two or more lobes. Diffuse symmetric interstitial infiltrates or areas of consolidation, cavitation, or pleural effusion suggest

bacterial superinfection. Pathologic findings in the trachea and bronchi are similar to those previously seen during acute uncomplicated disease, but bronchiolitis and alveolitis are also present.¹³²⁰ The laboratory findings in primary viral pneumonia are not specific. The erythrocyte sedimentation rate and the complete blood count are usually within normal ranges.

In nonfatal cases, initial improvement occurs from 5 to 16 days after onset of pneumonia. Resolution of radiographic changes can take up to 4 months.²²⁵⁴ Survivors can develop diffuse interstitial fibrosis with decreases in diffusion capacity of carbon dioxide and in arterial oxygen tension.^{1146,1657,2254} Influenza B virus can cause severe disease but does not seem to be associated with fatal primary viral pneumonia in normal individuals.^{534,2095}

Avian H5N1 influenza appears to follow a clinical pathway of primary viral pneumonia, although with a striking mortality of ~60% (updated regularly at http://www.who.int/csr/disease/avian_influenza/en/). As of February 1, 2013, 615 cases with 364 fatalities had been reported, resulting in a mortality rate of ~60%.⁹⁵

During the H1N1 pandemic in 2009, a small number of patients developed rapidly progressive primary viral pneumonia that led to acute respiratory distress syndrome and multiple organ failure, which was associated with high mortality.^{86,625,684,705,706,1635,1927} (see The H1N1 Pandemic in 2009 section). Histopathologic findings included diffuse alveolar damage (DAD) with hyaline membranes and septal edema, DAD with intense alveolar hemorrhage, and necrotizing bronchiolitis.^{625,1345,1847}

Combined Viral–Bacterial Pneumonia

Combined viral–bacterial pneumonia is quite common. The bacteria most often involved are *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Haemophilus influenzae*, although other micro-organisms can play a role.^{614,1320,1644,1827} (Fig. 41.4). Clinically, this syndrome may be indistinguishable from primary viral pneumonia, except that the symptoms of pneumonia appear somewhat after the influenza symptoms and chest radiographs are more likely to show pleural effusions. Virus has been recovered from the lungs and pleural fluid.^{1320,1347} The erythrocyte sedimentation rate is more frequently elevated than in primary viral pneumonia. Because there is no effective distinction between the two syndromes, the diagnosis depends solely on the demonstration of bacteria in the sputum, in fluid obtained at bronchoscopy, or in the pleural fluid. The case fatality rate for combined viral–bacterial pneumonia is 10% to 12%.^{136,510,1262,1644} Co-infection with influenza and *S. aureus* can have a fatality rate of up to 42%.¹⁷⁴¹

The available data suggest that bacterial pneumonia contributed significantly to the high mortality rate associated with the 1918 pandemic^{190,302,1272,1420} (see The Pandemic of 1918/1919—Spanish Influenza (H1N1) section). Bacterial superinfections were frequently observed with A(H1N1)pdm09 infections, in particular with fatal cases^{243,625,705,706,914,1254,1345,1599,1635,1847} (Fig. 41.4). The most common bacterial pathogens were *S. pneumoniae*, *S. aureus*, *H. influenzae*, and group A *Streptococcus*, similar to those found with seasonal influenza.

Influenza virus–infected mice experience a higher mortality rate upon *S. aureus* infection compared to mice not infected with influenza viruses.⁸⁹¹ In ferrets, influenza virus infections

increase the susceptibility to *S. pneumoniae* infection.¹³⁵⁹ The magnitude of this effect may vary among the influenza (sub) types: 9 out of 10 ferrets infected with an H3N2 virus and subsequently infected with pneumococcus developed sinusitis or otitis media, in contrast to only 1 of 11 ferrets infected with an influenza A H1N1 or influenza B virus.¹⁶²⁸

There are strains of *S. aureus* that secrete proteases capable of activating the infectivity of influenza virus by proteolytic cleavage of the HA. These strains play a synergistic role in experimental pneumonia in mice.^{2043,2044} Such protease-secreting bacterial strains could be an added pathogenic factor in combined viral–staphylococcal pneumonias in humans. An apparent increase in combined viral–bacterial pneumonias was being noted with the 2003–2004 influenza A H3N2 epidemic, perhaps coincident with the rapidly increasing impact of staphylococcal disease and emergence of methicillin-resistant *S. aureus*.¹⁶⁶⁷

Secondary Bacterial Pneumonia

In this syndrome, an individual recovering from a typical influenza illness develops shaking chills, pleuritic chest pain, and an increase in cough productive of bloody or purulent sputum.¹²⁶² Cyanosis and a marked increase in respiratory rate are less common than with primary viral pneumonia. Radiographic examination reveals local areas of lung consolidation but not diffuse pneumonia. Often, influenza virus is no longer recoverable, leukocytosis is common, and the erythrocyte sedimentation rate is elevated. This condition is generally amenable to antibiotic therapy, although a case fatality rate of about 7% has been described.¹²⁶²

Extrapulmonary Manifestations

Viremia

Viremia is highly unusual in influenza virus infections.^{1028,1397} Virus was isolated from the blood at low levels (present only in undiluted blood specimens) from a patient on the fourth day of influenza illness.¹⁴⁶⁵ Virus was present in barely detectable amounts in the blood of two patients with fatal primary viral pneumonia on the sixth day after the onset of illness and was recovered at necropsy from the liver and spleen of one patient.¹¹⁸³ In addition, the presence of viremia has been inferred because virus was present in low titer in extrapulmonary tissues such as heart, liver, spleen, kidney, adrenal glands, and meninges of patients dying of pneumonia.^{954,1737}

During the H1N1 pandemic in 2009, viremia (detected by RT-PCR) occurred rarely and was only observed in severe and fatal cases.^{1585,2070} Viremia and systemic spread is more common with avian H5N1 influenza, with PCR detection of virus from the blood in each of six patients tested.⁹⁵

Myositis

In adults, a diffuse myositis can occur with generalized pain, tenderness, and weakness of muscles, increased serum levels of muscle enzymes, myoglobinemia, and myoglobinuria.¹³⁹⁶ Acute renal failure sometimes follows. The pathogenesis of myositis remains uncertain.^{1018,1396} Although influenza virus has been recovered from muscle, the relation between the virus and myositis remains unclear. In children, myositis is usually localized to the gastrocnemius and soleus muscles and is characterized by pain on walking. Onset of myositis occurs as

respiratory illness wanes—the muscles are tender and swollen, serum levels of muscle enzymes are elevated, the course is usually benign and reversible, and light microscopic changes of muscle necrosis and inflammatory cell infiltrates are seen.⁴²¹

Cardiac Involvement

Influenza recovery from the heart of patients with myocarditis associated with fatal pulmonary infection is rare.^{1320,1581} Clinical findings and cardiac function studies in patients with severe pulmonary infection suggest that myocardial dysfunction is not a direct result of influenza A virus infection.^{200,1262,2070}

Reye Syndrome

Reye syndrome is a rapidly progressive noninflammatory encephalopathy and fatty infiltration of the viscera, especially the liver, which results in severe hepatic dysfunction with elevated serum transaminase and ammonia levels. This syndrome is seen following respiratory, varicella, and gastrointestinal viral infections. The onset of the central nervous system (CNS) and hepatic symptoms usually begins as respiratory tract symptoms wane. The case fatality rate varied between 22% and 42%.⁸⁵⁵ The etiology and pathogenesis of this syndrome are unknown. There is electron microscopic evidence of mitochondrial swelling.¹⁶¹² Influenza B virus infection is the most common antecedent infection. The disease associated with influenza B virus infection occurs in children ages 0 to 18 years (median age, 11 years) and is more frequently seen in rural than in urban areas.⁸⁵⁵ Salicylate administration is a critical cofactor in the development of Reye syndrome. The incidence of Reye syndrome after influenza virus infection in the salicylate era was estimated to be between 0.37 and 0.88 cases per 100,000 children younger than 18 years. This may have been underestimated because milder forms of Reye syndrome have been described.¹²¹⁸ There has been a dramatic decrease in Reye syndrome cases in the United States associated with reduced use of salicylates, which are now widely recognized to be contraindicated in influenza virus infection.

Central Nervous System Involvement

A wide spectrum of CNS disease has been observed during influenza A and B virus infections in humans,^{635,759} ranging from irritability, drowsiness, boisterousness, and confusion to serious manifestations such as psychosis, delirium, and coma. Febrile convulsions leading to hospitalization occur in children with and without underlying CNS abnormalities. The pathogenesis of these CNS symptoms is unclear. Nonspecific metabolic effects such as hypoxia resulting from severe pulmonary infection may contribute to the CNS signs and symptoms.

Two specific CNS syndromes accompany influenza infection: influenzal encephalopathy and postinfluenzal encephalitis.⁵⁴¹ Encephalopathy occurs at the height of influenza illness and may be fatal.⁴¹⁰ The cerebrospinal fluid (CSF) is usually normal, the brain at autopsy shows severe congestion, and histologic changes are minimal. Lungs of such patients show changes typical of influenza and yield virus in high titer. A subset of influenza encephalopathy has been described extensively in Japan and seen in other countries as an acute necrotizing encephalopathy with bilateral thalamic and cerebellar involvement.²²³⁴

The postinfluenzal encephalitic syndrome is extremely rare, occurring from 2 to 3 weeks after recovery from influenza.

Recovery is achieved in most cases. The association of postencephalitic syndrome with influenza virus infection is less certain because virus is no longer recoverable and initial serum specimens may already reflect a rising antibody titer.⁵⁴¹ Influenza A virus has only rarely been recovered from the brain or cerebrospinal fluid, and attempts to isolate it from the CNS of individuals dying of primary viral pneumonia have been unsuccessful.¹³²⁰

The syndrome of encephalitis lethargica followed by postinfluenzal encephalitic Parkinson disease was associated with the influenza epidemics of 1918 and the epidemics that followed.¹⁷⁰⁷ The epidemics of encephalitis lethargica followed the epidemics of influenza, which were followed, in turn, by postencephalitic Parkinson disease about 1 decade later.¹⁷⁰⁷ Experiments in animals suggest that avian H5N1 viruses can cause pathology similar to Parkinson disease.⁹¹¹

An increase in the incidence of Guillain-Barré syndrome (GBS), an acute neurologic disorder that causes muscle weakness and partial paralysis, has not been seen after influenza A or B virus epidemics (see the Reactogenicity of Seasonal Influenza Vaccines and Vaccines to A(H1N1)pdm09 Virus sections).

Infection During Pregnancy

Pregnant women in the second or third trimester have an increased risk of developing fatal influenza disease.¹⁵⁰⁵ The increased mortality is generally seen during the years after introduction of a new pandemic strain, as in 1918, 1957, and 2009,^{665,1807,2134,2265} although using a large data set, the impact can be appreciated in the interpandemic period.¹⁵⁰⁵ During the H1N1 pandemic in 2009, an increased risk of complication, hospitalization, and death was observed among pregnant and postpartum women, when compared to the general population.^{1261,1427,1887} Based on a systematic review, pregnant women infected with A(H1N1)pdm09 virus accounted for 6.3%, 5.9%, and 5.7% of hospitalizations, intensive care unit admissions, and deaths, respectively, although only approximately 1% of the population is pregnant at any given time.¹⁴²⁷ The risk for complications is greater during the later stages in pregnancy; among 56 pregnant women who died from A(H1N1)pdm09 virus infection in the United States from April through December 2009, four (7.1%) were in the first trimester of pregnancy, 15 (26.8%) in the second, and 36 (64.3%) in the third.¹⁸⁸⁷ Increased risks of adverse neonatal outcomes including preterm delivery and low birth weight were observed, particularly with severe maternal illness due to A(H1N1)pdm09 influenza.^{360,1887}

Virus is typically not recovered from the fetus, although in one case viral RNA was detected in the fetus of a woman who succumbed to infection with HPAI H5N1.⁶⁷⁶ Influenza virus itself has not been implicated as a cause of congenital defects.^{975,1297,1408} Although an increase in congenital anomalies and hematologic malignancies has been reported after influenza virus infection in pregnancy, no consistent association between specific defects or malignancies and influenza epidemics has emerged.^{49,669,712,1702}

Infection in Immunosuppressed Patients

Influenza viruses can cause severe disease in immunocompromised individuals,^{348,1251,1742,2240} but more often the illness resembles that seen in immunocompetent persons.¹³⁹³ Somewhat prolonged shedding of virus occurs in immunosuppressed persons.^{877,878,1742,2240}

In adults infected with human immunodeficiency virus (HIV)—most of whom were on antiretroviral therapy and had well controlled-HIV infections—the clinical outcomes of infection with A(H1N1)pdm09 virus (including the frequency of severe illness and death) were similar between HIV-infected and noninfected patients.^{1643,1730} In the United States, however, the hospitalization rate among patients co-infected with HIV and A(H1N1)pdm09 virus (3.4%) was higher compared to the HIV prevalence rate in the US adult population (0.45%).¹⁶⁴³ Among recipients of hematopoietic stem cell transplants or solid organ transplants, A(H1N1)pdm09 influenza caused an increased risk of severe illness with a high incidence of lower respiratory tract complications, and an increased risk of mortality.^{508,1109,1911}

Influenza B and C Virus Infections

Influenza B virus causes the same spectrum of disease as influenza A but there are less frequent epidemics so that its total impact in a pediatric population is roughly one-third that of influenza.⁹⁸⁶ Severe illness can occur^{56,1035,2268}; however, the frequency of serious influenza B virus infections requiring hospitalization is about fourfold less than that of influenza A virus. Influenza B virus illness predominantly involves adolescents and school-age children, but adults and the elderly can also be affected.^{56,323,629,633,635,722,1536} Myositis, Reye syndrome, and gastrointestinal symptoms appear to occur more commonly with influenza B than A virus infection.^{323,518,1017,1140}

Influenza C virus causes sporadic upper respiratory tract illness and is rarely associated with severe lower respiratory tract disease.¹⁴²² By early adulthood, most individuals (96%) have antibody to influenza C virus.¹⁵⁴¹ Administration of influenza C virus to volunteers induced mild coryza with some systemic symptoms.⁹³⁸ Of 170 children infected with influenza C virus, most (92%) were younger than 6 years of age.¹³⁴⁴ In infants and young children (particularly <2 years of age), complications of bronchitis, bronchiolitis, and bronchopneumonia that may require hospitalization have been reported^{655,1344}; nevertheless, influenza C virus is not a major cause of lower respiratory tract infection in children.

IMMUNOLOGY

The respiratory tract has multiple nonspecific protective mechanisms against influenza virus infection—including the mucin layer, ciliary action, and protease inhibitors—that may prevent effective cell entry and virus uncoating. The extremely short incubation period between infection and clinical illness implies that innate immunity or preformed cognate recognition components are important. Much of what we know about the protective components of immunity and events that terminate primary influenza infection is from murine models. To better understand immune responses to influenza infection and vaccination, systems biology approaches are now employed.^{169,192,738,939,976,1084,1348,1467,1468,1474,1836,1998,2205}

INNATE IMMUNE RESPONSES

In vertebrates, innate immune responses are a critical first line of defense against microbes. Innate immune responses can

broadly be divided into three steps: (1) microbe recognition by a pathogen recognition receptor (PRR), resulting in the production of type I IFN, chemokines, and cytokines; (2) activation of IFN-signaling pathways leading to the upregulation of IFN-stimulated genes, many of which have antimicrobial functions; and (3) the actions of cellular proteins with antimicrobial functions. Recent data also demonstrate high induction of IFN- λ upon influenza virus infection,⁹²⁴ suggesting a role for type III IFN in innate immune responses to influenza virus infections.

Pathogen Recognition Receptors (PRRs)

Microbes are recognized by PRRs, including Toll-like receptors (TLRs), RIG-I-like receptors, and NOD-like receptors (NLRs). Recognition of pathogen-associated molecular patterns by PRRs results in the activation of signaling pathways that ultimately converge on the expression of antimicrobial genes. Influenza virus infection is sensed by TLR3 in airway epithelium^{693,1161,1386,2281} and TLR7 in plasmacytoid dendritic cells,^{419,610,1214,1283,1386,2281} upregulating their expression. For example, high levels of TLR3 were found in the lungs of individuals who died after infection with A(H1N1)pdm09 virus.¹³⁴⁵

TLR3 (gene name: *TLR3*) senses double-stranded RNA (dsRNA) and acts through the adaptor molecule TRIF, thereby leading to the activation of IRF3, NF κ B, and the activator protein 1 (AP1) transcription factors. These three factors are critical in stimulating the expression of type I IFN and of pro-inflammatory cytokines. TLR7 (gene name: *TLR7*) recognizes single-stranded RNA (ssRNA), and relies on the adaptor protein MyD88 to induce NF κ B and IRF7, which subsequently induce the expression of type I IFN and pro-inflammatory cytokines. TLR7 is expressed in high amounts in plasmacytoid dendritic cells, and hence, may be critical for abundant IFN- α secretion, which is observed in response to influenza virus infection.^{419,951,1338,1339} By contrast, TLR3 may play a more significant role in the induction of NF κ B-dependent proinflammatory cytokines.¹¹⁶² Compared to wild-type mice, TLR3^{-/-} mice infected with influenza virus showed reduced levels of proinflammatory cytokines and increased virus titers in the lungs, but reduced mortality.¹¹⁶¹ This suggests that TLR3-dependent gene expression, potentiated in airway epithelium, may contribute to immunopathology associated with influenza virus infections.

Stimulation with TLR2 and TLR4 prior to influenza virus infection increases resistance to virus infection,¹⁸⁵⁹ and TLR4 signaling has been implicated in influenza viral pathogenicity.^{329,870} Immunization of mice with nanoparticles containing influenza HA protein in combination with ligands that signal through TLR4 and TLR7 induced higher levels of neutralizing antibodies and better protection against viral challenge than treatment with antigen and one ligand only⁹⁸⁵; hence, the interplay of B-cell responses and TLR4/7 signaling seemed to confer robust protection from influenza virus infection. TLR7 has also been shown to play a critical role in Th1-mediated immunogenicity triggered by inactivated whole influenza virus vaccine.⁶¹⁰ Despite these findings, the exact roles of TLRs in the induction of B- and T-cell responses to influenza virus infection remain somewhat controversial.^{774,1090,1260,1833}

RIG-I (gene name: *DDX58*) is activated by 5'-triphosphate groups on influenza viral RNAs.^{82,83,1652,1711} Once activated,

RIG-I interacts with the interferon β promoter stimulator-1 (IPS-1) protein at the mitochondrial membrane,¹⁵⁵¹ which leads to the stimulation of IRF3, IRF7, and NF- κ B activity. RIG-I expression increases in response to influenza virus infection; the expression of both RIG-I and IPS-1 is essential for the induction of type I IFN and upregulation of IFN-stimulated antiviral genes in mouse embryo fibroblasts.¹²⁵⁹ RIG-I is critical for virus recognition and type I IFN production in fibroblasts, conventional dendritic cells, and epithelial cells.^{987,1575}

The inflammasome, a complex of a NOD-like receptor and the ASC adaptor protein, is also activated by influenza virus infection, in a mechanism that may involve M2 ion channel activity.^{18,857,858,2059} Inflammasome activation leads to the cleavage and activation of procaspase-1, which in turn cleaves and activates certain cytokines, particularly IL-18 and IL-1 β . In human macrophages infected with influenza virus, IL-18 and IL-1 β release occurs in a caspase-1–dependent manner, consistent with inflammasome activation in response to infection.¹⁶⁶¹ In addition, these two cytokines are upregulated in bronchoalveolar lavage fluids of mice infected with influenza virus, an effect that was not observed in mice deficient in NLRP3 (the prototype NLR), ASC, or caspase-1.^{18,857,2059} Mice lacking different components of the inflammasome show increased mortality and delayed viral clearance after influenza virus infection.^{18,857,858,2059}

NS1 Interferes with the Activation of PRRs

The activation of PRRs stimulates the synthesis of type I IFN, chemokines, and cytokines. Influenza viruses, primarily through their NS1 protein, have evolved mechanisms to counteract the induction of antiviral responses. Viruses with truncated, deleted, or mutated NS1 proteins induce higher levels of IFN than their wild-type counterparts.^{241,380,381,474,703,767,1074,1075,1385,1507,1575,1652,1914,2032} Early studies suggested that NS1 may accomplish this function by sequestering dsRNA, which activates transcription factors such as ATF-2/c-Jun, NF κ B, and IFN regulatory factors (IRFs) that stimulate IFN- β production.^{1271,1275,2032,2198} However, little dsRNA seems to be produced in influenza virus infected cells,^{1652,2211} and mutation of the NS1 amino acids that are critical for dsRNA binding have only limited effects on IFN levels.³⁸¹ Rather, NS1 seems to regulate IFN production through two other mechanisms: interference with RIG-I activation and signaling, and interference with the processing of cellular pre-mRNAs.

The NS1 protein interferes with RIG-I activation,^{703,1385,1575,1652} most likely by interacting with RIG-I directly,^{1385,1652} and/or by interacting with TRIM25,⁵⁷⁰ a factor that is required for RIG-I ubiquitination and activation. Moreover, influenza virus infection prevents the activation of IRF-3^{436,1073,1575,2032} and blocks IPS-1 (a function that is carried out by the viral polymerase complex⁸⁹⁴). Interestingly, chickens seem to lack RIG-I,⁶⁵ which may, at least in part, explain their high susceptibility to influenza virus infections.

NS1 also controls IFN levels by blocking splicing,^{545,1270,1694} polyadenylation, and nuclear export of cellular pre-mRNAs (including IFN- β mRNA).^{545,1530,1690,1693} This function requires the interaction of NS1 with the 30-kDa subunit of the cleavage and polyadenylation specificity factor (CPSF; gene name: *CPSF4*).^{295,378,1073,1483,1530} Two amino acids in NS1 at positions 103 and 106 are critical for CPSF binding and affect virulence.^{378,952,1073} Strain-specific differences in

the ability to interfere with the maturation of pre-mRNA^{952,1073} may contribute to viral pathogenicity. For example, the NS1 of the A(H1N1)pdm09 virus does not efficiently block host gene expression,^{719,952} a function that was restored upon the introduction of three human virus-like amino acids at positions 108, 125, and 189, which also increased binding to CPSF.⁷¹⁹ Interestingly, however, these mutations attenuated the virus in mice.⁷¹⁹

IFN Signaling

Type I IFN acts in an autocrine and paracrine manner through the ubiquitously expressed IFN- α/β receptor (IFNAR). IFNAR loss results in high susceptibility to influenza virus infection^{600,1080} but, interestingly, increases survival of mice to secondary bacterial infections.¹⁸³⁵ Activation of IFNAR by type I IFN stimulates the Janus kinase (JAK)/signal transducers and activators of transcription (STAT) pathway. JAK/STAT signaling induces the formation of a transcription factor complex that upregulates the expression of IFN-stimulated genes. The suppressor of cytokines signaling (SOCS) proteins 1 and 3 are upregulated upon influenza virus infection^{1621,1672} and counteract type I IFN signaling, likely by interfering with the JAK/STAT pathway. As a consequence, reduced levels of SOCS-3 or lack of this protein reduce influenza virus titers in cell culture.¹⁶²¹

Proteins with Antiviral Activity

IFN-induced stimulation of the JAK-STAT pathway results in the induction of IFN-stimulated genes, including those encoding TLRs (suggesting positive feedback loops), PKR, OAS, RNaseL, ISG15, Mx proteins, Viperin, and IFITM.

PKR

Activation of dsRNA-activated protein kinase R (PKR; gene name: *EIF2AK2*) leads to the phosphorylation of the translation initiation factor eIF2 α and the subsequent shutdown of protein synthesis. Influenza viruses inhibit PKR activation,^{120,749,1271,1280} and a mutant virus lacking NS1 was virulent in PKR^{-/-} mice, but not in wild-type mice.¹²⁰ NS1 may block PKR activation through direct binding^{1207,1391,2037} and/or sequestration of dsRNA.^{749,1271} However, as stated earlier, little dsRNA has been detected in influenza virus–infected cells; in addition, PKR is now also known to be activated by ssRNA with 5′-triphosphate groups,¹⁴⁷⁵ suggesting that influenza viral RNAs may activate both RIG-I and PKR. PKR activity may also be affected by the influenza virus M2 protein, which binds to the cellular PKR inhibitor p58(IPK), resulting in increased PKR phosphorylation.⁶⁸³ The role of p58(IPK) in the regulation of PKR activity and influenza pathogenesis is underscored by the finding of increased lung pathology and mortality in influenza virus–infected p58(IPK)^{-/-} mice, compared to wild-type mice.⁶⁴⁴

OAS and RNase L

Two members of the 2′-5′-oligoadenylate synthetase (OAS) family, the OAS1 (gene name: *OAS1*) and OAS-like (gene name: *OASL*) genes are induced upon influenza virus infection.^{1381,1390} Activated OAS stimulates RNase L (gene name: *RNASEL*), a single-strand-specific nuclease that degrades cellular and viral RNA, resulting in antiviral activity. Pretreatment of cells with IFN- β had no significant effect on a wild-type virus, but restricted a virus with a mutation in the RNA-binding

domain of NS1.¹³⁹⁰ This restriction was relieved in RNase L^{-/-} mouse cells or in cells treated with siRNA to RNase L.¹³⁹⁰ These findings demonstrate that the RNA-binding domain in NS1 controls the antiviral functions of OAS/RNase L.

ISG15

Interferon-stimulated gene 15 (ISG15; gene name: *ISG15*) is conjugated (ISGylated) to its target proteins; this alteration may interfere with the normal (enzymatic) function of the target protein. For example, ISG conjugation promotes IRF3 activation by preventing ubiquitination and subsequent degradation of the transcription factor.¹⁸⁴⁵ ISG15^{-/-} mice are more susceptible to infection with influenza A and B viruses than are control mice,^{1127,1187} and treatment of cells with siRNAs to ISG15 partially impairs IFN-induced antiviral activity.⁸⁴² Mechanistically, conjugation of ISG15 to NS1 appears to interfere with NS1 function in several ways: it impairs dimerization of the NS1 RNA-binding domain; disrupts NS1 binding to dsRNA, U6 snRNA, and PKR; interferes with NS1-mediated disruption of antiviral gene expression; and inhibits NS1 association with importin α .^{2038,2360} In contrast to the influenza A virus NS1 protein, the influenza B virus NS1 protein blocks the antiviral activity of ISG15 by interfering with E1 ligase for ISG15 modification activity.^{2342,2343}

Mx Proteins

Mx proteins are IFN-induced GTPases of the dynamin superfamily. They confer resistance to influenza virus infection^{598,723,1228,1942} by interfering with viral replication.^{725,727,2383} In particular, they interfere with the replicative activity of the viral ribonucleoprotein complex,^{427,2110} perhaps by interacting with and wrapping around the nucleoprotein.^{724,2110} Mx proteins have been identified in several mammalian and avian species; most, but not all, inhibit influenza viruses (reviewed in⁷²⁶).

Of note, influenza viruses differ in their sensitivity to Mx proteins: in general, avian influenza viruses are more sensitive to inhibition by Mx proteins than human influenza viruses.⁴²⁷ The replication complex of an HPAI H5N1 virus was significantly affected by human MxA protein,⁴²⁷ and mice expressing murine Mx1 protein were protected against infection with HPAI H5N1.²¹⁰⁸

Most conventional laboratory mice, including most commercially available knock-out mice, lack a functional Mx gene.¹⁹⁴⁰ This fact should be taken into account when interpreting data obtained with such mice.

IFITM

The interferon-induced transmembrane (IFITM) proteins 2 and 3 (gene names: *IFITM2* and *IFITM3*) are ubiquitously expressed cellular proteins with roles in immune cell signaling, oncogenesis, and cell adhesion. Overexpression of IFITM2 and 3 inhibits influenza virus, most likely during cell entry.¹⁶⁹ IFITM3 is modified by palmitoylation; deletion of its palmitoylation site abrogates its antiviral activity against influenza virus.²³²⁹ The underlying mechanism is currently not known.

Viperin

Viperin (gene name: *RSAD2*) is an IFN-stimulated, ER-associated protein expressed in many species from fish to mammals. It inhibits several viruses, including influenza

virus, most likely by disrupting lipid rafts, the sites of influenza virus budding.²¹⁹⁷

Other Strategies to Counteract Innate Immune Responses

The PDZ Domain of the NS1 Protein

A large-scale sequencing project of avian influenza viruses identified a PDZ ligand domain motif at the carboxy-terminal four amino acids of NS1.¹⁵⁴⁵ This motif is recognized by PDZ domain proteins, a large family of proteins that play multiple roles in cellular processes. Most human influenza viruses possess an RSKV motif, in contrast to the ESEV motif found in most avian influenza viruses. When tested in the background of a laboratory-adapted human H1N1 virus (A/WSN/33), the PDZ ligand domain motifs of pandemic 1918 and HPAI H5N1 viruses conferred increased virulence to viruses in mice,⁸⁹⁸ demonstrating the significance of this sequence for influenza viral pathogenicity. Interestingly, the observed differences in virulence did not correlate with IFN expression levels,⁸⁹⁸ suggesting that the PDZ ligand domain motif in NS1 affects pathogenicity through a currently unknown mechanism. By contrast, the PDZ ligand domain motif had little effect on the virulence of an HPAI H5N1 in mice and chickens.²³⁸⁰ Replacement of the avian virus ESEV motif with the human virus RSKV motif in a low pathogenic avian H7N1 virus attenuated the virus in mice.¹⁹³⁰ The ESEV motif binds to the PDZ domain proteins Scribble, Dlg1, and MAGI-1, -2, and -3.¹²⁴⁴ Scribble possesses proapoptotic function and interaction of NS1 with Scribble reduces apoptosis,¹²⁴⁴ suggesting that the PDZ ligand domain motif may regulate the induction of apoptosis in virus-infected cells. Moreover, the PDZ ligand domain motif affects Mx levels,¹⁹³⁰ suggesting a role in the regulation of innate immune responses.

The A(H1N1)pdm09 viruses encode a truncated NS1 protein that lacks the 11 C-terminal amino acids. Reconstitution of this region and thus the PDZ domain does not significantly affect replication, pathogenicity, or transmission in animal models.^{718,1592}

NS1 Activates the PI3K/Akt Pathway

PI3K (phosphoinositide-3-kinase) and its most prominent substrate, the serine/threonine protein kinase Akt, regulate many different cellular events including apoptosis, cell metabolism, and proliferation. In addition, PI3K plays a role in the transcriptional regulation of IFN-stimulated genes, and in the regulation of TLR-mediated cytokine production.

The NS1 proteins of influenza A,^{475-477,713,714,717,1211,1852,1853} but not influenza B viruses,⁴⁷⁶ activate the PI3K/Akt pathway. Although this pathway was believed to have antiviral function, its activation is also required for efficient influenza virus replication.^{475,1852} NS1 binds to p85 β , a regulatory subunit of PI3K; several residues in NS1 have been identified that are critical for this interaction.^{713-715,1211,1851,1853} One study demonstrated that NS1 interacts with phosphorylated Akt, resulting in increased Akt activity.¹³³⁷ Activation of the PI3K/Akt pathway may delay the induction of apoptosis,^{476,1268,1851,2363,2365} although another study suggested that this process is not regulated through the PI3K pathway.⁸⁹⁹ Two recent studies also suggest roles for PI3K in clathrin-independent endocytosis⁵⁶⁰ and endosomal acidification,¹³¹⁶ suggesting that PI3K activation may facilitate virus infection through these processes.

Additional Roles of NS1 in Pathogenicity

In addition to the described functions and key amino acids, several studies have identified amino acids in NS1 that contribute to virulence and possibly also innate immune responses through currently unknown mechanisms.^{869,926,1213,1681,1788,1831,1832,1956} For example, the differences in pathogenicity in pigs between NS genes derived from HPAI H5N1 or a non-H5N1 virus were traced to a single amino acid at position 92 of NS1, with glutamic acid at this position conferring higher pathogenicity than aspartic acid.^{1831,1832}

Two internal deletions in NS1 affect pathogenicity. Since 2000, most HPAI H5N1 viruses possess a deletion of amino acids 80 to 84 in their NS1 proteins, which enhances virulence.¹²⁵⁸ Of note, during the generation of viruses possessing this deletion, the D92E mutation was co-selected,¹²⁵⁸ suggesting a functional relationship between these two potential virulence determinants. In addition, HPAI H5N1 viruses isolated in 2004 to 2005 in Thailand possessed both the 5-amino-acid deletion at positions 80 to 84 and the D92E mutation.²⁰⁰⁷ In virus-infected cells, the 5-amino-acid deletion and the D92E mutation affected responses to TNF- α , or the induction of IFN, respectively.¹²¹⁰ The other deletion in NS at nucleotides 612 to 626 (resulting in amino acid deletions in both the NS1 and NS2 proteins) also affects IFN induction and virulence.²³⁷⁸

Differences Between NS1 Proteins in Their Ability to Affect Innate Immune Responses

NS proteins differ in their ability to counteract cellular IFN responses. Compared to the NS1 proteins of human viruses, the NS1 proteins of HPAI H5N1 viruses induce higher levels of proinflammatory cytokines, such as TNF- α and IFN- β ,³⁰⁰ and confer higher pathogenicity in pigs.¹⁸³¹ These findings suggest that the NS1 protein of highly pathogenic viruses may cause the cytokine imbalance that was observed in victims of H5N1 infection in Hong Kong in 1997.^{95,399,2069,2345} The NS gene of the 1918 pandemic virus interfered with the transcription of IFN-regulated genes more efficiently than did a control virus possessing an NS gene derived from a human virus.^{132,612}

Role of Mitogen-Activated Protein Kinase (MAPK) Signaling Pathways in Influenza Virus Infection

Currently, four MAPK signaling pathways are recognized including the extracellular signal regulated kinases 1/2 (ERK1/2), the c-jun-N-terminal kinase (JNK), p38, and ERK5. Activation by external stimuli leads to the phosphorylation of kinases in the signaling cascades, and the phosphorylation of transcription factors such as c-Jun or ATF-2, which are critical for the upregulation of IFN- β , RANTES, and other factors with functions in innate immune responses and apoptosis.

All four MAPK pathways are activated upon influenza virus infection.^{611,794,1107,1223,1273,1321,1421,1665,2280} The p38 and ERK1/2 MAPK pathways are strongly activated by HPAI H5N1 viruses, in contrast to H1N1 viruses.¹¹⁷² ERK1/2 is important for efficient viral replication^{1276,1316,1568,1665,2280} since the influenza HA protein-mediated activation of ERK1/2^{1315,1317} appears to be critical for efficient nuclear export of viral ribonucleoprotein complexes.¹⁶⁶⁵ In addition, ERK1/2 may phosphorylate NS1, which might be critical for efficient virus replication.⁷¹⁶ By contrast, JNK, p38, and ERK5 have antiviral activity through their roles in the regulation of apoptosis and the expression of

cytokines and chemokines; p38 may also play a role in influenza virus internalization.¹³¹⁴

The PB1-F2 Protein

For some influenza viruses, PB1-F2 increases viral pathogenicity, inflammation, and the frequency and severity of bacterial co-infections in mice.^{340,891,1356,1899,2349} These phenotypic differences likely result from the currently known functions of PB1-F2 in the induction of apoptosis and replicative ability.

PB1-F2 localizes to mitochondria,^{291,623,2295} where it interacts with the ANT3 (adenine nucleotide translocator 3) and VDAC1 (voltage-dependent anion channel 1) proteins,²³⁴⁸ and induces the formation of membrane pores with subsequent changes in mitochondrial permeability.^{271,783} The resulting induction of apoptosis, which is primarily observed in immune cells,^{291,623,2348} may contribute to the increased virulence upon PB1-F2 expression. However, one study suggests that this induction of apoptosis is strain specific and may not be the major function of PB1-F2.¹³⁵⁵

PB1-F2 enhances inflammatory responses, as demonstrated by an increased influx of inflammatory cells in lungs of mice infected with an influenza virus expressing the PB1-F2 protein from the 1918 pandemic influenza virus.¹³⁵⁶ Enhanced inflammatory responses were observed with PB1-F2 peptides (encompassing the 27 C-terminal amino acids) of an HPAI H5N1 virus and the pandemic 1918, 1957, and 1968 viruses, but not for that of a recent human H3N2 virus.¹³⁵⁵ The PB1-F2 protein of the 1918 pandemic virus encodes serine at position 66, instead of the asparagine commonly found among human influenza viruses at this position. Serine at position 66 of PB1-F2 increased virus titers and pathogenicity, immunopathology, cytokine levels, and the severity of secondary bacterial pneumonia in mice, resulting in higher mortality.^{339,340} The increased pathogenicity of the serine variant likely resulted from delayed immune responses, as assessed by transcriptional profiling studies.³³⁹

PB1-F2 co-localizes and interacts with the polymerase PB1 protein. Lack of PB1-F2 expression results in altered intracellular localization of PB1 and decreased viral polymerase activity,¹³⁵² which may affect virulence. These effects are strain specific and cell type specific.¹³⁵⁷

Innate Immune Cells

Innate immune cells—including macrophages, neutrophils, dendritic cells, and natural killer (NK) cells—play an important role in the control of influenza virus infections. These cells contribute to virus clearance through phagocytosis or lysis of infected cells, the production of cytokines and chemokines, and/or the stimulation of adaptive immune response. Macrophages and neutrophils phagocytose infected cells and produce chemokines and cytokines. Macrophages also act as professional antigen-presenting cells.^{561,748,1033} Infection with highly pathogenic influenza viruses leads to pronounced infiltration of macrophages and neutrophils into the lungs of infected individuals^{95,2345} or animals.^{76,1068,1639,2105} Inhibition of macrophage and neutrophil phagocytosis,⁷⁴⁸ or depletion of alveolar macrophages,²¹⁰⁵ increases virus titers and mortality in mice. By contrast, mice lacking CXCR2 (a receptor on neutrophils) can clear influenza viruses, although they fail to recruit neutrophils to the lung.²²⁰² Macrophages may also contribute to excessive inflammation and immunopathology since they produce high

levels of cytokines/chemokines upon infection with highly pathogenic influenza viruses.^{300,848,1180,1405,2340,2368} In addition, macrophages produce nitric oxide synthetase 2 (NOS2), which exacerbates influenza virus infections.^{913,1912}

Dendritic cells (DC) present antigens to other immune cells, acting as messengers between the innate and adaptive arms of the immune system. Upon influenza virus infection, they are the major professional antigen-presenting cell and, hence, CD4 and CD8 T cell-stimulating cell population.^{128,129,1538} DCs can acquire antigen through direct infection by influenza viruses^{114,128,733,1538} or through the phagocytosis of infected epithelial cells.^{13,128,739,1790} DCs also produce type I IFN and various cytokines and chemokines.⁷³⁹ In particular, large amounts of type I IFNs are produced by plasmacytoid dendritic cells, a subset of DCs that is rapidly recruited into the lungs of mice infected with influenza viruses.²²⁵⁶ The maturation and type I IFN production of respiratory dendritic cells are affected by the NS1 protein.^{420,528,767}

NK cells release perforin and granzymes that lead to the lysis of infected cells; in addition, they produce chemokines and cytokines. A large body of data indicates a role for NK cells in innate immunity to influenza virus infections,^{7,43,446,608,697,817,1088,1243,1308,1384,1886,1957,1958} and NK cell depletion renders mice and hamsters more susceptible to influenza infections.¹⁹⁵⁸ NK cells detect influenza viruses through interaction of the NK receptor NKp46 with HA,^{7,43,1308,1384} and mice lacking NKp46 show increased morbidity and mortality upon influenza virus infection.⁶⁰⁸ The HA proteins of different subtypes may trigger different activation programs in NKs: while an H1 HA triggered NK cell-mediated lysis, additional activation signals for killing were required with an H5 HA.⁷ Influenza viruses appear to interfere with NK functions by infecting them^{696,1313}; infected NK cells have reduced killing capacity, produce lower amounts of chemokines and cytokines, and eventually die. In several cases of influenza virus infection, low levels of peripheral NK cells were detected^{414,779}; however, it is not clear if these cells were killed by influenza viruses or migrated to respiratory organs.

In summary, several immune cell populations have functions that may in parallel dampen and aggravate influenza virus infection. Most likely, a fine balance between temporal, spatial, and quantitative regulation of these cell populations and regulatory factors will contribute to infection outcome.

ADAPTIVE IMMUNE RESPONSES

Mice that lack both B and T cells succumb to influenza virus infection,^{428,2060,2230} whereas those lacking either immune cell type can control, although not necessarily clear, influenza virus infections.^{115,480,481,1222,1726} These findings demonstrate that adaptive antibody- and T cell-mediated immune responses are important to clear influenza virus infections.

Strain-specific immunity to influenza can be of long duration as reflected in the age-specific attack rates of pandemics with reemergence of a strain, as in the A/USSR H1N1 pandemic in 1977, recall cellular immunity to distant infection,¹¹⁵⁸ and neutralizing antibodies to the pandemic 1918 virus or its descendants that were detectable 90 years later.^{734,890,1070,1309,1890,2341}

Although murine models clearly demonstrate immune responses that are cross-reactive among influenza strains of the

same subtype, the classic teaching in humans based on experiencing recurrent influenza infections is that adaptive immunity is quite strain specific. The rapid drift of B-cell epitopes in influenza viruses due to immune selection suggests that there is strong evolutionary pressure exerted by the collective population immunity. Similar pressure on T-cell epitopes has been suggested, but there appears to be less variability in these sites.²¹⁶⁷

However, two recent observations suggest immunity that is cross-reactive among influenza viruses of different subtypes in humans. The first is the demonstration of common neutralizing epitopes in the stem of the hemagglutinin.^{485,1565,1897,1999,2230} The second is a strong resistance to infection of adults with live, attenuated vaccines with the HA and NA of potentially pandemic strains—for example, H5N1, H7N7, H9N2—that vaccinees have never been infected with.⁹⁷⁸

Humoral Immunity

Serum antibodies play an important role in resistance to and recovery from influenza illness in humans, or at the very least are a strong correlate of immunity.^{346,349,616,617,1282,1452} Indicative of the importance of antibody is that immunization of mothers during pregnancy provides protection in infancy through placental transfer of antibody.²³⁴⁷ Upon infection with influenza viruses, antibodies to the HA, NA, NP, and M proteins are produced, of which antibodies to HA are the most important for virus neutralization.^{364,615,616,1674} HA and NA are the primary protective antigens, and antibodies against these glycoproteins are the main mediators of resistance to virus challenge.^{346,349,503,1452}

The level of serum antibody to HA and NA correlates with resistance to illness and with restriction of influenza virus replication in the respiratory tract of humans.^{326,351,923,980,1456} In addition to the levels of serum antibodies, their avidity is likely important for optimal protection.^{187,525,900,1067,1808}

HA antibodies can prevent infection by neutralizing the infectivity of the virus, typically by interfering with HA-mediated receptor binding or fusion.^{66,485,1067,1999,2035,2051,2052,2165,2326} Most neutralizing antibodies are believed to bind conformational epitopes. The X-ray crystallographic structures of several HA/antibody complexes have been resolved now^{138,485,540,1999} and allow the structural interpretation of antibody binding to HA (for more information on the HA antigenic sites, refer to the Antigenic Drift of the HA Protein section). Although antibodies to HA play the primary role in protection against influenza virus infections, NA antibodies mediate an antiviral effect by limiting virus release and hence restricting virus spread.^{350,1029,1456,1675,2226} NA-specific antibodies may have thus ameliorated the severity of the Hong Kong influenza in 1968,¹⁴¹⁴ when an H3N2 influenza virus emerged following a reassortment event with a previously circulating H2N2 virus.

Passively transferred monoclonal antibodies to M2 are protective in mice^{1433,2077} and M2 antibodies develop in naturally infected humans,^{139,526,2092} although the titers are typically low. M2 is highly conserved among influenza A viruses, suggesting its potential as a universal influenza vaccine (see later discussion and Vaccines section). Antibodies to NP have been detected in individuals,^{498,685,2000,2302} and vaccination with NP leads to faster virus clearance and reduced mortality in mice.^{67,491,502,504,558,1138,1252,1796,2036,2068,2114,2115,2266,2366} Information on the three-dimensional structure of NP²³¹⁷ allowed the mapping of several monoclonal antibodies onto NP.²¹⁴⁶ Infection with influenza viruses also elicits antibodies to M1.^{364,1019}

A protective effect of transplacentally acquired antibody has been inferred from the correlation between age at the time of symptomatic influenza A virus infection in infants and level of maternally transmitted antibody measured in cord serum.¹⁶⁸² In addition, vaccination of pregnant women against A(H1N1)pdm09 virus increased the percentage of newborns with protective immunity to influenza virus compared to babies born to unvaccinated mothers,^{1683,2382} further suggesting vertically acquired passive immunity.

A vaccine that elicits heterosubtypic immunity against influenza A viruses of different subtypes would no longer require frequent changes in the composition of influenza vaccines. Heterosubtypic immunity was first demonstrated in the 1960s when infection with an influenza virus was shown to reduce virus titers and pathology of a challenge virus belonging to a different subtype in mice.¹⁸²⁰ In contrast, sequential heterotypic infections have been demonstrated in children in a single season²²⁷¹; the prior receipt of a heterotypic cold-adapted vaccine did not alter the pattern of virus shedding with subsequent vaccination while the second dose of the same strain shows no evidence of reinfection. Broadly neutralizing antibodies to HA have been described^{344,485,984,1565,1566,1898,1999,2065,2195,2230} that bind to a highly conserved region in the stem region of HA2, and block the low pH-induced conformational changes that mediate membrane fusion. Their broad neutralizing activities and the apparently low rate of escape mutants^{344,1999,2195} make HA2 an interesting target for a universal vaccine (see Vaccines section). Cross-protective antibodies against the ectodomain of M2 have also been described.^{393,506,514,530,849,1432,1477,2077} Although M2 is immunogenic and antibodies to it are protective in mice,^{393,506,514,849,1432,1477,2077} the potential of M2 vaccines in other animal models^{514,1706} and humans¹⁸¹⁶ is less well established.

A potent antibody-dependent cellular cytotoxicity (ADCC) response has been demonstrated following influenza infection,⁷⁴⁷ but it has not been integrated into our conceptualization of the protective immune response to influenza.

Cellular Immunity

The role of cellular immunity in clearance of influenza virus has been well defined in the murine model but is less well understood in humans.^{979,1370}

There are two major subsets of effector lymphocytes in humans. The first subset mediates cytotoxicity that is restricted by class I histocompatibility antigens and has the CD8⁺ phenotype. CD8⁺ T cells (cytotoxic lymphocytes, CTLs) eliminate virus through two mechanisms: direct killing of virus-infected cells, and the production of proinflammatory cytokines.¹¹²⁴ CTLs appear in the blood of infected individuals or those vaccinated with a live virus on days 6 to 14 and largely disappear by day 21.⁴⁹⁷ Most studies have examined memory CTLs, which are detected *in vitro* by stimulation of peripheral blood lymphocytes with antigen. These CTLs can exhibit a cross-reactive pattern of virus specificity (i.e., they lyse target cells infected with influenza A viruses belonging to any subtype, but not target cells infected with influenza B virus).^{165,473,501,1096,1370,2313,2325,2385} The cross-reactivity of CTL responses likely contributed to the lower infection rate of the elderly with A(H1N1)pdm09 virus, as 50% of influenza-derived T cell epitopes are similar between the pandemic 1918 and 2009 viruses.^{662,664} Indeed, both CD8⁺²⁰⁹⁹ and CD4⁺⁶⁰⁹ cells reactive with A(H1N1)

pdm09 virus were present prior to infection with this virus. However, a more specific subpopulation of CTLs lyses only cells infected with homologous virus. Depending on human leukocyte antigen (HLA) haplotype, individuals differ considerably in the peptides that their CTLs can recognize.¹³⁷¹ Memory CTLs characterized after infection or vaccination of humans have the cross-reactive pattern of cytotoxicity. The pre-challenge level of memory CTLs did not correlate with susceptibility to infection or illness after experimental administration of wild-type virus, but did correlate with accelerated clearance of virus from the respiratory tract of humans.¹³⁷⁰

The other class of T cells is restricted by histocompatibility class II antigens and has the CD4⁺ phenotype^{965,1966}; thus, it belongs to the T-helper class of T cells. CD4⁺ T cells are helper T cells, providing help to B cells for antibody production and to class I-restricted CTLs for their proliferation.^{1132-1134,2325} Helper T cells specific for M or NP antigen can provide help to B cells secreting HA antibody^{1132-1134,1798} and, in this manner, can augment the antibody response to protective antigens. CD4⁺ T cells also have cytolytic activity^{661,1979} that is most likely mediated through perforin, rather than Fas:FasL.^{179,180}

The important role of CD4⁺ T cells in immunity to influenza virus infection has been defined by studies in CD8⁺ T cell-deficient animals, which can clear influenza A virus by a CD4⁺ T cell-dependent mechanism.^{115,480,481,1222} Passively transferred influenza virus-specific CD4⁺ T-cell clones require functional B cells to clear an ongoing influenza virus infection. Thus, the primary antiviral activity of the CD4⁺ T cell is probably to help B cells produce antiviral antibodies. Because CD4⁺ T cells recognize many epitopes on influenza viral proteins, a large number of T cells are available to provide such help.²⁴⁰

CD8⁺ T cells can mediate clearance of influenza A virus infection in CD4⁺ T cell-deficient animals.^{481,1726} In mice lacking CD4⁺ T cells, primary CD8⁺ T cell responses are not significantly affected,¹⁷²⁶ in contrast to CD8⁺ T cell memory formation and recall.¹¹² Animals deficient in both CD4⁺ and CD8⁺ T cells succumb to infection,^{428,2060} indicating that nonspecific mediators of immunity are not sufficient in the absence of T cells to contain and clear influenza A virus infection. The number of CD8⁺ T cell epitopes on viral proteins is much more restricted than the number of B-cell or CD4⁺ T cell epitopes. Cytolysis of influenza virus-infected cells can also be mediated by antibody plus complement and antibody-armed lymphocytes.^{747,1697,1760} While CD8⁺ T cells play a critical role in virus elimination, they may induce significant immunopathology.^{429,1123}

Lymphoproliferation is another measure of the cellular response to influenza. Lymphocytes responsive to influenza virus antigens have been isolated from the blood and lower respiratory tract secretions of influenza virus-infected humans, but only the former have been studied extensively.^{949,2325} Lymphocyte blastogenic responses to influenza antigens in humans increase after influenza A virus infection, beginning between the third and sixth day after infection,⁴³⁰ and return to baseline levels by day 28.

Invariant NKT (iNKT) cells (also referred to as type I NKT cells) are the most prevalent NKT cells in mice. Their name reflects the invariant T cell receptor α chain expressed by these cells. Activated iNKT cells appear to play roles in both cell- and antibody-mediated immunity,¹¹⁰⁸ and produce large amounts of interferons and cytokines such as IFN- γ and

IL-4.²¹⁰⁹ Stimulation of iNKT in mice reduced virus titers compared to control mice,⁸¹⁸ and mice lacking iNKT cells show a higher mortality rate than wild-type mice.⁴⁰³ Moreover, use of an iNKT activator as an adjuvant for influenza vaccination results in increased immunogenicity and protection.¹⁰⁸⁶ These findings suggest a contribution of iNKT cells to immunity against influenza viruses.

Influenza A virus infection can depress skin test reactivity to common antigens used to assess cutaneous delayed hypersensitivity.¹⁷¹⁰ In addition, depression of the peripheral blood lymphocyte blastogenic responses to mitogenic and antigenic stimulation^{430,1196} is seen during the acute stage of infection and early convalescence. Despite this transient depression of delayed hypersensitivity and blastogenic responses to noninfluenza antigens or mitogens, influenza virus-specific cellular responses develop. The mechanisms underlying the depression in the function of lymphocytes in influenza virus infection indicated earlier have not been defined, but influenza A virus infection can abortively infect human lymphocytes *in vitro*¹⁸⁸ and possibly *in vivo*.²²⁵¹

Mucosal Antibody Response

Francis³⁵² was the first to detect neutralizing activity to influenza in nasal secretions. He subsequently showed that resistance to experimental influenza A virus infection in mice was mediated by an antibody in bronchial secretions. The neutralizing antibody in the nasal secretions of humans is primarily locally produced IgA.^{44,1756} Antibody to both HA and NA can be detected in local secretions, but the former is easier to detect.³⁴⁹ It has been proposed that IgA antibodies can act intracellularly during transcytosis to the apical surface to inhibit virus replication and thus participate in clearance of infectious virus from the epithelial cells and lumen of the respiratory tract.^{1351,1720} IgA and IgG may switch in relative importance between the upper and lower respiratory tract as shown in a murine model of the protective role of passive neutralizing antibody.¹⁷²¹

During primary viral infection, IgA, IgG, and IgM hemagglutinin-specific antibodies can be detected in nasal washes by use of an enzyme-linked immunosorbent assay (ELISA). IgA and IgM antibodies are detected more frequently than IgG antibody.¹⁴⁵⁷ Most of the HA-specific IgA and IgM antibodies are actively secreted locally, whereas local secretion has been demonstrated only infrequently for IgG antibody, although a receptor for IgG transport is present on bronchial epithelial cells.²³²⁷ Individuals with a local IgA response also have a serum IgA response. Local IgA antibody stimulated by natural infection is detectable for 3 to 5 months after infection, and there is local IgA memory for influenza antigen.¹⁴⁵² After secondary infection, local antibody is also primarily of the IgA isotype, those with a local IgA response also have a serum IgA response, and the magnitude of the serum IgA HA antibody response correlates with that of the local response.

The presence of local IgA antibody induced by infection with an attenuated virus correlates with resistance of volunteers to infection and illness after challenge with a virulent wild-type virus.⁹³⁵ Challenge of children with an attenuated live vaccine shows similar findings.^{162,163} Resistance to experimental wild-type infection also correlates with the level of local HA antibody present at the time of virus administration, with IgG and IgA each contributing to resistance.³²⁶

SURVEILLANCE

Surveillance efforts in humans have increased considerably in recent years. These efforts are coordinated by the WHO through the Global Influenza Surveillance and Response System (GISRS; formerly the Global Influenza Surveillance Network, GISN) that was founded in 1952 and currently includes five Collaborating Centres (in Atlanta, Beijing, London, Melbourne, and Tokyo), 136 National Influenza Centres in 106 countries, 11 H5 Reference Laboratories, and four Essential Regulatory Laboratories (http://influenzacentre.org/centre_GISN.htm). The National Influenza Centres collect more than 175,000 samples each year from patients with influenza-like illness and submit approximately 2,000 representative samples per year to the Collaborating Centres for antigenic and genetic characterization. These data are used to monitor antigenic drift and resistance to antiviral compounds. Based on surveillance, antigenic, and genetic data, vaccine viruses are recommended by the WHO each February and September for the Northern and Southern Hemispheres, respectively.

Summaries of influenza activity are published in the *Morbidity and Mortality Weekly Report* from the Centers for Disease Control and Prevention (CDC) during the influenza season and in the *Weekly Epidemiologic Record* published by the WHO. An even more current report of influenza epidemiology is available at the CDC FluView website (www.cdc.gov/flu/weekly). These reports are linked with reports of pneumonia and influenza deaths in 121 US cities to monitor the emergence of an influenza epidemic. Surveillance in the face of highly pathogenic H5N1 viruses has focused not only on human illness, but also on causes of mortality in domestic and wild birds. There continues to be a strengthening of routine surveillance particularly in China and Southeast Asia to identify the emerging strains that inform the choice of vaccine components for the coming influenza season. The threat has propelled countries around the world to prepare for an influenza pandemic. The US plan can be found at www.hhs.gov/nvpo/pandemicplan; since its release in 2005, the plan has been updated to reflect the guidelines established during the H1N1 pandemic in 2009.

DIAGNOSIS

Several diagnostic tests are available to detect influenza A and B viruses, including viral culture, reverse transcriptase-polymerase chain reaction (RT-PCR), immunofluorescence assays, and rapid antigen testing. Growth of samples in eukaryotic cells is still considered the gold standard but requires 3 to 10 days (pertinent cell lines are described in the Virus Propagation section). This time can be reduced to 1 to 3 days. Influenza virus in culture can be detected by using immunoassays or RT-PCR. PCR-based diagnosis is significantly more sensitive than culture. RT-PCR is now the method of choice in many diagnostic labs since it combines several attractive features: it is highly sensitive (which, on the other hand, requires good laboratory practices and stringent controls to avoid or monitor for cross-contamination); it has reasonable test times since data can be obtained within 1 day; and it can be designed to distinguish between different types and subtypes, depending on the sets of oligonucleotides used. In addition, multiplexing is possible to test multiple samples at once, or to test for more than one viral RNA segment in one reaction.

In recent years, multiple rapid influenza diagnostic tests have been developed and approved for the analysis of human samples. Most of these are immunoassays that detect the NP antigen. Some of these can distinguish between influenza A and B viruses. Currently available rapid influenza diagnostic tests provide results within 5 to 30 minutes, but have a low sensitivity rate of about 40% to 70%. Indirect immunofluorescence assays are not widely used for routine diagnostics since they are not conducive to high-throughput testing or multiplexing. Overviews of currently recommended diagnostic tests and rapid tests can be found at <http://www.cdc.gov/flu/professionals/diagnosis/>, <http://www.cdc.gov/flu/professionals/diagnosis/rapidlab.htm>, and http://www.who.int/csr/disease/avian_influenza/guidelines/RapidTestInfluenza_web.pdf. The standard protocols for the diagnosis of influenza viruses from avian species (some of which are also used for the diagnosis of human samples) can be found in the OIE Manual of Diagnostic Tests and Vaccines for Terrestrial Animals 2010 (<http://www.oie.int/international-standard-setting/terrestrial-manual/access-online/>).

The available tests can be carried out with nasopharyngeal or throat swabs, bronchial washes, nasal or endotracheal aspirate, or sputum. The tests can differ in their sensitivity and specificity for different types of specimens. In general, nasopharyngeal specimens collected with a swab are more sensitive than throat swab samples. Samples should be collected as soon as possible after the onset of symptoms. In adults, virus shedding typically declines on days 4 to 5 after the onset of symptoms, making virus detection difficult. Children typically shed virus for longer periods of time.

Serologic testing to assess influenza A virus subtypes and HA antigenic drift variants is typically carried out by using hemagglutination inhibition (HI) or microneutralization assays. These assays are used by the WHO because of their reliability, but are not recommended for standard diagnostic testing because of their complexity.

ANTIVIRALS

Four antiviral compounds—the M2 ion channel inhibitors amantadine and rimantadine, and the neuraminidase inhibitors oseltamivir and zanamivir—are currently approved in many countries for use in humans. Additional neuraminidase inhibitors such as peramivir and laninamivir received temporary emergency approval during the H1N1 pandemic in 2009, and/or are licensed in Japan and Korea. Most H1N1 and H3N2 viruses currently circulating in humans are sensitive to neuraminidase inhibitors; in contrast, more than 90% of currently circulating H1N1 and H3N2 viruses are resistant to the ion channel inhibitors. Accordingly, this latter class of compounds is no longer recommended for use in humans.⁵³⁵

Amantadine and Rimantadine

Amantadine hydrochloride and rimantadine, an analog of amantadine, were licensed for prophylactic and therapeutic use against influenza A virus in humans in the United States in the 1960s. These compounds are active against all subtypes of influenza A virus, but not against influenza B or C viruses.²⁰⁹

Amantadine and rimantadine are adamantane derivatives. Both compounds have a tricyclic structure with an amine side

group. They inhibit virus replication by blocking the acid-activated ion channel formed by the virion-associated M2 protein.^{110,757,758,872,1659,1660,1997,2192,2239} The primary antiviral action of these compounds results from blocking the flow of H⁺ ions from the acidified endosome into the interior of the virion, a process necessary for release of ribonucleoprotein complexes into the cytosol for transport to the nucleus. These compounds also inhibit the replication of viruses that have multiple basic amino acids at their HA cleavage site by inhibiting M2 ion channel activity in the *trans*-Golgi network, which prevents the premature low pH-induced conformational change of HAs cleaved by furin.^{316,1764,1782}

Until 2004, amantadine and rimantadine were used to treat infections caused by seasonal influenza A viruses.^{25,575,720,1056,1057} Symptomatic improvement, including accelerated clearance of local symptoms and fever, occurs about 1 day earlier in treated than in untreated patients, and peripheral airway dysfunction also resolves more quickly. Accelerated clearance of symptoms was seen in children infected with an H3N2 virus treated with rimantadine compared with control children who received an antipyretic.⁷²⁰

Amantadine and rimantadine have also been used for prophylaxis against seasonal influenza A virus infections.^{25,36,387,431,915,1141,1412,1622,1646,1725,1828,1908–1910,2073,2074,2381} During an epidemic involving both influenza A H1N1 and H3N2 viruses, amantadine and rimantadine protected against influenza-like illness (78% and 65%, respectively), documented influenza illness (91% and 85%, respectively), and influenza A virus infection (74% and 66%, respectively).⁴³¹ Lower efficacy rates against documented illness (70%) and infection (39%) were observed for amantadine prophylaxis during an H1N1 virus epidemic in 1977.¹⁴¹²

At the recommended adult dose of amantadine or rimantadine (i.e., 100 mg twice daily orally), significant adverse effects have not been reported (reviewed in⁹⁰⁴).

Resistance to adamantanes is conferred by mutations at position 26, 27, 30, 31, 34, or 38 of M2, with mutations at position 27, 30, or 31 found most frequently.^{110,757,758,1658,2008} Structural studies of the M2 ion channel in the absence and presence of amantadine^{210,1805,1976} show that the channel is relatively narrow at position Val27, but opens into a wider cavity that is lined by Ala30 and Ser31 (among other amino acids), providing structural information on the effect of mutations at these critical positions.

In experimental settings, resistant variants emerge rapidly and frequently.^{788,1587,1588,1590,2176} Until 2004, the rates of resistance among seasonal influenza viruses remained low,^{102,389,2379} although adamantane-resistant variants had been isolated from infected individuals.^{408,493,765,776,893,1325,1587,1629,1774,1775,1803,1861} During the 2003 to 2004 season, the rate of adamantane-resistant seasonal H3N2 viruses increased to 12.3%.¹⁷⁵ One year later, more than 90% of seasonal H3N2 viruses had acquired adamantane resistance,^{176,416,761,799,1175,1383,1773} typically conferred by a Ser-to-Asn mutation at position 31 of M2. At that time, many seasonal H1N1 viruses remained sensitive to ion channel inhibitors.^{73,416,799} In 2009, the seasonal H1N1 viruses were largely replaced by the novel A(H1N1)pdm09 viruses, which are resistant to adamantanes.²⁵³ Hence, the H1N1 and H3N2 viruses circulating in humans since 2009 are resistant to adamantanes, thus use of these compounds is no longer recommended.^{535,537}

Several avian H5 viruses isolated before the emergence of the currently circulating HPAI H5N1 viruses were found to be resistant to amantadine.²¹⁷⁶ For HPAI H5N1 viruses, the rate of adamantane resistance varies greatly depending on their geographic origin.^{199,299,772,801,853,866,1163,1686} Based on sequence analysis, avian H6 viruses should be sensitive to amantadine⁸⁶⁶; among H7 and H9 viruses, some were identified with mutations known to confer resistance to adamantanes.⁸⁶⁶ Many European swine viruses of several lineages are resistant to adamantanes,^{1099,1804} likely because their M genes belong to the same phylogenetic lineage.¹⁰⁹⁹ The pandemic 1918 virus is sensitive to ion channel inhibitors.^{1714,2103}

Neuraminidase Inhibitors

The neuraminidase inhibitors oseltamivir and zanamivir were approved in the United States in 1999.¹⁴⁶⁰ They are effective against influenza A and B viruses and are currently recommended for “all persons with suspected or confirmed influenza requiring hospitalization or who have progressive, severe or complicated illness regardless of previous health or vaccination status”.⁵³⁵

The recommended treatment differs by age group (summarized in⁵³⁵). Five-day courses are recommended for therapeutic treatment, while longer courses may be used for prophylactic treatment. Oseltamivir is administered orally as a granulated powder in capsules. The standard dose for adults is 75 mg, twice daily. Oseltamivir is currently approved for persons aged 1 year and older. During the H1N1 pandemic in 2009, emergency approval was granted in the United States (<http://www.cdc.gov/h1n1flu/recommendations.htm>), Europe (http://www.ema.europa.eu/docs/en_GB/document_library/EPAR_-_Product_Information/human/000402/WC500033106.pdf), and several other countries for the use of oseltamivir in infants younger than 1 year of age. Zanamivir is provided as a powder and administered by inhalation. For adults, two daily inhalations (5 mg each) are recommended for the treatment of infections, whereas one daily inhalation of 10 mg is recommended for prophylactic purposes. Zanamivir is approved for persons aged 7 years or older. Adverse effects to neuraminidase inhibitors include vomiting, abdominal pain, and nausea, but are generally mild^{762,763,1642,2171} (reviewed in⁴⁶²).

The first NA inhibitors included DANA (2-deoxy-2,3-dihydro-*N*-acetylneuraminic acid; Neu5Ac2en) and its *N*-trifluoroacetyl analog FANA, which were effective *in vitro*^{1379,1600} but did not inhibit replication of influenza viruses in animals.¹⁶⁰¹ After resolution of the NA structure,^{338,2145} DANA served as the lead compound in the rational design of drugs targeting the NA protein. Replacement of the 4-hydroxyl group on DANA with a guanidino group filled the unoccupied pocket in the NA active site with an inhibition constant (K_i) of 2×10^{-10} mol/L,^{2168,2262} resulting in zanamivir (5-(acetylamino)-4-[(aminoiminomethyl)-amino]-2,6-anhydro-3,4,5-trideoxy-D-glycero-D-galacto-non-2-enonic acid, also called 4-guanidino-Neu5Ac2en).

An additional NA inhibitor, oseltamivir, was developed during the following years. This was achieved through the discovery and use of a hydrophobic pocket in the enzyme-active center that could accommodate lipophilic groups necessary to improve the inhibitor's oral bioavailability.^{1032,1834} The resulting compound, oseltamivir, is administered in the form of a pro-drug, oseltamivir phosphate; in the liver, oseltamivir phosphate

is converted into the active form, oseltamivir carboxylate (reviewed in³⁸³). Finally, an intravenously administered NA inhibitor, peramivir, was approved for emergency use in hospitalized patients during the H1N1 pandemic in 2009 but is not presently considered an option (except for Japan and Korea).⁹⁰⁸

The efficacy of oseltamivir and zanamivir in the treatment and prevention of influenza A and B virus infections have been assessed in a number of studies.^{25,201,461,535,904,916-918,1328,1875,2040} Both compounds are also effective against A(H1N1)pdm09 viruses.^{704,909,1887} In general, the initiation of treatment within 48 hours of the onset of symptoms is critical^{360,434,517,1177,1179,1261,1887,2334}; however, treatment later in infection may still provide some benefit.^{1173,1177-1179,1365,1887}

For uncomplicated infections with seasonal influenza viruses, both drugs reduce the duration of illness by about 1 day (if treatment is started early). In addition, the amount of virus shed appears to be reduced. Several studies suggest that neuraminidase inhibitors also reduce the risk of severe complications.^{272,736,778,936,953,1177-1179,2243}

Oseltamivir is effective against HPAI H5N1 viruses. It improves the outcome of mice^{659,1186,2324} and ferrets^{151,658} infected with highly pathogenic viruses. Data from infected individuals suggest that treatment with NA inhibitors improves survival rates; early treatment was again noted as a critical factor.^{2,796,957,959,1220,1829} Based on these findings, NA inhibitors are recommended by the WHO as the primary treatment for human HPAI H5N1 virus infections (http://www.who.int/csr/disease/avian_influenza/guidelines/pharmamanagement/en/index.html). Although treatment with NA inhibitors improves the outcome of HPAI H5N1 infections in humans, a significant percentage of individuals still succumb to the infection; in one example, even early treatment of infected individuals resulted in the emergence of resistant variants (see later discussion) and death of the treated patients.⁴⁰⁰ Higher doses and prolonged treatment with neuraminidase inhibitors have shown additional benefits in animal studies^{151,2324} and also in infected individuals.²

Oseltamivir may also be efficacious in the prophylaxis or treatment of human infections with avian viruses of the H7 subtype. During the H7N7 virus outbreak in The Netherlands in 2003 (see Transmission of Avian Influenza Viruses to Humans section), health care workers and their close contacts were prophylactically treated with oseltamivir, which likely prevented severe infections¹³⁷⁶; the reported cases of conjunctivitis^{546,1085} and death²¹³⁵ were limited to individuals who did not take oseltamivir.

Treatment with neuraminidase inhibitors does not appear to prevent the development of humoral antibodies, which is critical to protect against reinfection with antigenically similar viruses. Ferret studies have demonstrated protection against reinfection,^{151,658} and seroconversion has also been noted in individuals.^{171,257}

Resistance to Neuraminidase Inhibitors

Variants with reduced sensitivity to oseltamivir or zanamivir can be selected experimentally,^{72,143,334,687,691,1368,1383,1950,2021} and have been isolated from patients treated with neuraminidase inhibitors (see later discussion). Mutations that confer resistance to neuraminidase inhibitors are summarized in [e-Table 41.1](#); most of these mutations map to catalytic sites in NA (R118, D151, R152, R224, E276, R292, R371, and Y406;

N2 numbering),²¹⁴⁵ or framework sites (E119, R156, W178, S179, D/N198, I222, E227, H274, E277, N294, and E425; N2 numbering)²¹⁴⁵ that stabilize the active site. The most frequently identified mutations are R292K or E119V for H3N2 viruses,^{35,686,1367,2064} and H274Y for H1N1 viruses.^{35,686,1367,2064} Most oseltamivir-resistant viruses remain sensitive to zanamivir.

Resistance to zanamivir is extremely rare in treated patients,⁶⁹⁰ likely because of the structural differences between zanamivir and oseltamivir.^{337,1767} However, several viruses have been isolated that are resistant to both zanamivir and oseltamivir (e-Table 41.1), including these following 5 viruses. (1) An A(H1N1)pdm09 virus isolated from an immunocompromised child possessing H274Y and I222R mutations that were acquired during treatment with oseltamivir, and subsequent treatment with zanamivir, respectively; the I222R mutation rendered the virus less susceptible to zanamivir, oseltamivir, and peramivir (see Other Antivirals Against Influenza section).²¹²⁷ (2) Another A(H1N1)pdm09 virus with H274Y and I222R mutations was isolated from an immunocompromised child sequentially treated with oseltamivir and zanamivir; retrospective analysis revealed that both mutations had emerged before the initiation of zanamivir treatment.¹⁵¹² (3) H274Y/I222V mutations were reported for oseltamivir-resistant viruses isolated from two individuals who developed A(H1N1)pdm09 virus infection after prophylactic treatment with oseltamivir.²⁴⁷ (4) In an infant with no history of neuraminidase inhibitor treatment, an influenza B variant possessing a D197E (D198E in N2 numbering) mutation in NA was detected, in addition to wild-type virus.¹⁵⁴⁴ While viruses with a D197N mutation are known to confer resistance to oseltamivir,^{686,751,879} the D197E mutation had not been described. Of note, the D197E mutation conferred resistance to oseltamivir, zanamivir, and peramivir (see Other Antivirals Against Influenza section).¹⁵⁴⁴ The crystal structures of the D197 (wild-type) and D197E (resistant) variants have been resolved with and without inhibitor,¹⁵⁴⁴ and revealed that the D197E mutation affects the interaction with the *N*-acetyl group of sialic acid and NA inhibitors. (5) Zanamivir treatment of a ferret experimentally infected with an HPAI H5N1 virus yielded a zanamivir-resistant variant possessing a Q136L mutation in NA.⁸⁵² This mutation also conferred reduced sensitivity to oseltamivir.⁸⁵²

Overall, the rate of resistance to oseltamivir remained relatively low until 2007 to 2008, and resistance was observed more often with H1N1 viruses^{689,1961,2233} than with H3N2^{88,377,879,1051,1563,1961} or influenza B viruses.⁸⁷⁹ Only 8 of 2287 influenza A and B isolated from humans during routine surveillance between 1999 and 2002 showed reduced susceptibility to oseltamivir.¹⁴¹⁶ Another analysis of 1050 viruses isolated during surveillance in 2000 to 2002 found no mutations at positions known to confer resistance to neuraminidase inhibitors.¹⁴³⁸ A Japanese study reported resistance rates of 0.3% to 2.2% for viruses isolated in 2003 to 2007,¹²⁸⁹ whereas a global surveillance study of viruses isolated in 2004 to 2007 reported a resistance rate of 0.4% (12/3261).¹⁸⁴⁴ Another study of almost 2,000 patients treated with oseltamivir found resistance rates of 0.33% and 4.0% for viruses isolated from adults or children, respectively.³⁵ Resistance emerges frequently after prolonged treatment of immunocompromised patients, in whom the viruses replicate for extended periods of time.^{88,248,352,457,690,800,879,1382,1543,1563,2233}

During the 2007 to 2008 season, an increase in the number of oseltamivir-resistant H1N1 viruses was noted: in the

United States, 6.4% of isolates were resistant,¹⁸⁴⁴ while this number was even higher in Europe (with a resistance rate of ~20%) (http://ecdc.europa.eu/en/activities/surveillance/EISN/Newsletter/SUN_EISN_INFL_Bulletin_2008week16.pdf). In Europe, large differences were reported from country to country, with resistance rates between 1% in Italy and 68% in Norway.^{1092,1377} In 2008, 64% of seasonal H1N1 viruses tested in the Southern Hemisphere were resistant to oseltamivir,⁸⁵¹ and by March 2009, 1291 of 1362 seasonal H1N1 viruses analyzed had acquired resistance (http://www.who.int/csr/disease/influenza/H1N1webupdate20090318%20ed_ns.pdf). Clinical data indicate that oseltamivir-resistant H1N1 viruses are comparable in their severity to oseltamivir-sensitive viruses,^{194,317,417,755,1377} a finding that is consistent with studies in ferrets.⁷³²

In 2009, the oseltamivir-resistant H1N1 viruses were largely replaced by A(H1N1)pdm09 viruses. Most A(H1N1)pdm09 viruses are sensitive to neuraminidase inhibitors; however, up to 1% of viruses are oseltamivir resistant.^{89,218,222,247,248,352,457,745,871,1166,1382,1512,1933,2057,2064,2083,2127,2188}

Currently, most HPAI H5N1 viruses are sensitive to neuraminidase inhibitors, although several resistant variants have been isolated.^{400,464,606,636,800,801,853,1164} Of particular concern, avian surveillance studies have identified a number of HPAI H5N1 viruses with NA mutations that are known to confer resistance to neuraminidase inhibitors.¹⁵⁷⁸

Early studies indicated that viruses resistant to oseltamivir are attenuated in animal models, as demonstrated for lab-adapted H1N1 viruses,^{5,142} seasonal H1N1^{787,892} and H3N2 viruses,^{160,234,786,2021} an avian H4N2 virus,⁶⁹¹ and artificially generated viruses.²³²¹ Based on these findings, viruses resistant to neuraminidase inhibitors were not expected to out-compete the viruses circulating at the time. This assumption was consistent with the finding that oseltamivir-resistant viruses isolated from treated individuals did not transmit efficiently among humans (exceptions include an oseltamivir-resistant influenza B virus that may have arisen spontaneously or was transmitted from a treated patient,⁷⁵¹ and a community cluster of oseltamivir-resistant A(H1N1)pdm09 viruses.¹¹⁶⁶ Therefore, the rapid spread of oseltamivir-resistant seasonal H1N1 viruses in 2007 to 2008 was unexpected. However, these viruses possess additional mutations in NA (V234M and R222Q) that compensate for the loss of viral fitness due to the H274Y mutation.¹⁴⁷

In animal models, some oseltamivir-resistant A(H1N1)pdm09 viruses appear attenuated,⁴⁵⁰ while others are comparable in their pathogenicity and transmissibility to oseltamivir-sensitive A(H1N1)pdm09 viruses^{732,1052,1830}; the latter finding raises concerns that the resistant variants may supersede sensitive viruses, as was observed in 2007 to 2008 with seasonal H1N1 viruses. This concern is potentiated by increasing numbers of A(H1N1)pdm09 viruses possessing an S247N mutation that confers reduced sensitivity to oseltamivir and zanamivir.⁸⁵⁰ In an oseltamivir-treated patient, this mutation was found in combination with the H274Y mutation, resulting in extremely high resistance to oseltamivir.⁸⁵⁰

Combination Therapy

Although a number of influenza viruses have acquired resistance to adamantane or neuraminidase inhibitors, HPAI H5N1 viruses remain largely sensitive to both classes of compounds. Therefore, the combined use of adamantanes and neuraminidase inhibitors has been assessed in several *in vitro* and *in vivo*

studies.^{574,657,865,867,1323,1425} The combination of amantadine and oseltamivir was well tolerated in volunteers,¹⁴²⁵ and superior to monotherapy in terms of efficacy in mice.^{867,1323} Similarly, the combination of rimantadine with oseltamivir, zanamivir, or peramivir provided additive effects in cell culture⁶⁵⁷ and mice.⁵⁷⁴ Combination therapy could reduce the rate of emergence of resistant variants, as demonstrated in one study in cell culture.⁸⁶⁵

Other Antivirals Against Influenza

Peramivir, a neuraminidase inhibitor that is administered intravenously, received market authorization in Japan and Korea in 2010. In several other countries, including the United States, peramivir is currently in clinical trials⁵⁴ (<http://www.clinicaltrials.gov/ct2/show/NCT00958776?term=biocryst%2C+peramivir&rank=1>; accessed 06/05/2011). During the H1N1 pandemic in 2009, peramivir was available in the United States by Emergency Use Authorization (which expired in June 2010).^{135,789} Its efficacy has been assessed in mice and ferrets,^{1878,2346} and limited data on peramivir use in humans suggest a reduction in the duration of symptoms.^{74,213,789} Several mutations that confer resistance to oseltamivir also render those viruses resistant to peramivir (e-Table 41.1).

Laninamivir, a long-lasting inhaled NA inhibitor, is effective against oseltamivir-resistant influenza viruses.^{2204,2304} It is licensed in Japan^{1102,2304} and is in clinical trials in other countries.^{2204,2304}

T-705 (favipiravir) is an antiviral compound currently in phase II clinical trials in the United States (http://www.fujifilmholdings.com/en/pdf/investors/library/ff_announcement_20100215_001.pdf); in Japan, a phase III clinical trial has been completed (<http://www.clinicaltrials.jp/user/showCteDetailE.jsp?japicId=JapicCTI-090934>). It has favorable pharmacokinetics in cell culture¹⁸⁹⁵ and is effective against influenza A, B, and C viruses,^{564,1877,2023} including HPAI H5N1 viruses sensitive or resistant to oseltamivir.^{1053,1891,1896} T-705 inhibits the viral polymerase⁵⁶⁵ but, unlike ribavirin, does not affect cellular DNA or RNA polymerases.⁵⁶⁵ T-705 may be attractive for combination therapy with a neuraminidase inhibitor.¹⁸⁹⁶ Other targets include both viral and host pathways involved in influenza replication.⁷⁶⁰ An example would be the host-encoded proteases that cleave the influenza HA²³⁶⁴ (see HA cleavage section).

VACCINES

Vaccination is one of the most effective methods for preventing influenza virus infections and complications.³⁵⁵ Both inactivated and live attenuated vaccines are available against seasonal influenza viruses. These vaccines are currently trivalent, that is, they contain influenza A virus components of the H1N1 and H3N2 subtypes, and an influenza B virus component. Trivalent inactivated vaccines can be used for persons older than 6 months of age, while live attenuated vaccine is currently approved in the United States for healthy, nonpregnant individuals 2 to 49 years of age. In 2009, monovalent vaccines to A(H1N1)pdm09 virus were used widely. In the 2010 to 2011 season, A(H1N1)pdm09 virus became part of the trivalent vaccine and replaced the former seasonal H1N1 component. In addition, several vaccines to HPAI H5N1 viruses have been

approved. Other vaccines to H5, H7, and H9 viruses are in development.

Seasonal Inactivated Vaccines

Based on the immune status of the populations, and on antigenic and genetic information about circulating viruses (obtained through surveillance studies), the vaccine strains are recommended each year by the WHO (see Surveillance section). Since this decision has to be made more than 6 months prior to the influenza season, the selected vaccine strains occasionally differ antigenically from the viruses circulating during the subsequent influenza season. Limited antigenic match between the selected vaccine strains and the actually circulating strains may result in low efficacy (see Efficacy of Seasonal Influenza Vaccines section). After vaccine virus selection, so-called seed strains are generated that possess at least the HA and NA genes of the selected vaccine strains, and the remaining genes from the A/Puerto Rico/8/34 (A/PR/8/34; H1N1) virus, which confers a high level of growth in eggs.¹⁷⁴⁰ Traditionally, these seed viruses were generated by co-infecting cells with A/PR/8/34 virus and the donor virus of the HA and NA genes, and subsequent selection with antibodies to select viruses with the desired gene constellation. Although not yet used widely, reverse genetics methods (see Reverse Genetics section) can be used to accomplish this task faster and in a more controlled manner. As an alternative to these reassortant vaccine viruses, some countries use the WHO-recommended wild-type viruses for vaccination.

Most vaccine viruses are grown in the allantoic cavity of embryonated chicken eggs; in this system, however, they may acquire mutations in HA that can change the antigenic properties of the virus (see Virus Propagation and Host Cell-Mediated Selection of Antigenic Variants sections). In Europe and in the U.S., vaccines produced in MDCK cells are now also marketed. Several theoretical advantages exist for preparation of vaccine in mammalian cells including maintaining the mammalian HA phenotype and relative easiness of capacity expansion compared to egg-based vaccine production.²²⁶⁷

For vaccine virus production in embryonated chicken eggs, virus present in the allantoic fluid is purified and concentrated by zonal centrifugation or column chromatography and inactivated with formalin or beta-propiolactone. The resulting preparations are referred to as whole virus vaccine; due to their reactogenicity, whole virus vaccines are no longer used widely. Vaccine virus preparations may be further disrupted by treatment with chemicals (split vaccine) and partially purified to remove viral ribonucleoprotein complexes (subunit vaccine). Split and subunit vaccines are often collectively referred to as subvirion vaccines. In addition, so-called virosomal subunit vaccines can be generated by treating viruses with detergent, followed by ultracentrifugation to remove viral ribonucleoprotein complexes. After the extraction of detergent, membrane vesicles form that contain the HA and NA proteins.²²⁵⁰ Collectively, these purification procedures have greatly reduced the incidence of local and systemic reactions.

The quantity of immunoreactive HA in each dose is standardized to contain the amount recommended by the Advisory Committee on Immunization Practices, which is usually 15 μ g per component for adults and older children or 7.5 μ g for children younger than 3 years. The quantity of NA is not standardized because this glycoprotein is highly labile during

purification and storage.^{1012,1015} Each 0.5-mL dose of vaccine contains approximately 10 billion virus particles, and one egg yields one to three doses of vaccine. Vaccine also contains variable but small quantities of endotoxin, egg-derived protein, free formaldehyde, and most have thiomersal preservative, all of which do not appear to contribute to the reactogenicity or toxicity of the vaccines for humans. Inactivated vaccines are administered intramuscularly or, less often, subcutaneously or intradermally.

Seasonal Live Attenuated Vaccines

A live attenuated vaccine based on the A/Ann Arbor/6/60 (A/AA/6/60; H2N2) and B/Ann Arbor/1/66 (B/AA/1/66)^{108,472,1294,1451} viruses was developed in the United States and approved in 2003.^{108,1517,2080} A different live attenuated vaccine based on the A/Leningrad/134/17/57 and B/USSR/60/69 viruses has been used in the Russian Federation since the 1960s.^{16,1011,1014}

The A/AA/6/60 master donor virus was developed by passage of the wild-type virus at progressively lower temperatures in primary chicken kidney cell cultures until a mutant was identified that replicated efficiently at 25°C, a temperature restrictive for the replication of wild-type virus.^{1294,1295} The donor virus is temperature sensitive (*ts*; i.e., restricted in its replication at 38°C to 39°C, temperatures permissive for the replication of wild-type virus); cold adapted (*ca*; i.e., replicates efficiently at 25°C); and attenuated (*att*; i.e., restricted in its replication in the upper and lower respiratory tract of ferrets). The attenuated B/AA/1/66 master donor virus was developed by using a similar approach.

For the A/AA/6/60 master donor virus, the *ts* and *att* phenotypes are each defined by mutations in the PB2, PB1, and NP proteins,^{929,931} while the mutations that define the *ca* phenotype have not been identified. For the B/AA/1/66 master donor virus, the *att*, *ts*, and *ca* phenotypes are defined by mutations in the PA, NP, and M1 proteins⁸²³; the PA and NP⁸²³ proteins; or the PB2, PA, and NP proteins,²⁹⁴ respectively. The type A and type B master donor viruses differ by only seven or eight amino acids from the respective wild-type viruses; however, each of the characterized phenotypes is conferred by at least two mutations in different proteins, and reversion to wild type has not been observed.^{1010,1453,2152}

The attenuated A/Leningrad/134/17/57 virus was developed through 17 sequential passages in embryonated chicken eggs at 25°C. It differs by eight amino acids from the parental virus, which map to the PB2, M1, M2, and NS2 proteins (one amino acid change each), and the PB1 and PA proteins (two amino acid changes each).¹⁰⁶² The *ts* phenotype is conferred by mutations in the polymerase proteins.^{874,1047} The *ts* phenotype of the attenuated B/USSR/60/69 virus is defined by mutations in the PB2 and PA genes.¹⁰⁴⁸

Originally, seed viruses for vaccine production were generated by co-infecting, for example, the A/AA/6/60 master donor virus with the recommended vaccine viruses, followed by selection of reassortant progeny viruses at 25°C (restrictive for replication of wild-type virus) in the presence of an H2N2 antiserum, which inhibits replication of viruses bearing the surface antigens of the attenuated A/AA/6/60 master donor virus. In the United States, live attenuated vaccine viruses are now generated by using reverse genetics methods. Vaccine viruses are then grown in embryonated eggs, filtered, and concentrated. The vaccine is administered intranasally by spray.

Shedding of live attenuated viruses on days 1 to 2 post-vaccination is frequent in young children, but decreases with age.^{111,144,1043,1045,1194,1307,2031,2152} So far, only one case of virus transmission has been reported.²¹⁵²

Reactogenicity of Seasonal Influenza Vaccines

For inactivated vaccines, local or systemic allergic reactions to vaccine components are rare,^{126,1460,1594} and are primarily due to residual egg protein.^{1460,1594} Reactions generally occur within the first 24 hours and last for 1 to 2 days; they include systemic manifestations such as fever, malaise, myalgia, and headache, as well as local manifestations such as pain, erythema, induration, and tenderness at the inoculation site. The reactogenicity of influenza B virus vaccine is similar to that of influenza A virus.^{20,643,1156,1546} In children, whole virus vaccines cause more systemic reactions than subvirion vaccines^{127,166,382,1154,2273}; for children younger than 12 years of age, subvirion vaccines are therefore recommended. Cell culture-grown vaccines are comparable in their reactogenicity to egg-grown vaccines.^{27,673,1597,1598,1718} More recently developed adjuvants, MF59 and AS03, have increased local reactogenicity. For live attenuated vaccines, mild symptoms including stuffy or runny nose, sore throat, and/or mild fever have been reported.^{103,108,536,902,1517,1553,1554,2080}

An increase in reported cases of GBS (see Central Nervous System Involvement section) occurred in the United States in 1976 to 1977 during vaccination to the swine H1N1 virus that infected recruits in New Jersey^{1318,1754,1771,1815,2260} (see Interspecies Transmission section). About 1 in 100,000 individuals who received the vaccine against the 1976 swine H1N1 influenza virus developed GBS, with a relative risk in vaccine recipients about four- to eightfold greater than that in unvaccinated subjects^{1318,1771,1815}; these findings led to the cessation of the vaccination program. Typically, the risk of GBS after influenza virus vaccination is very small.^{710,950,966,1928,1929} Preliminary data from the A(H1N1)pdm09 vaccination program in 2009 suggests a definable but minimal risk of GBS.²⁵⁰

In vaccinated individuals, exacerbated illness (as observed after measles or respiratory syncytial virus vaccination) does not occur. There has been a single instance in which vaccinated school-aged children had more influenza-related lower respiratory tract illness than their unvaccinated counterparts.⁹¹² Inactivated influenza virus vaccines otherwise have a consistent record of efficacy and safety.

Immunogenicity of Seasonal Influenza Vaccines

The immunogenicity of a vaccine is significantly affected by prior exposure to the antigen. In unprimed individuals (such as children or persons with no or limited previous exposure to the respective antigen), higher amounts of antigen are required to elicit satisfactory levels of antibody. Thus, two doses of inactivated vaccine are recommended for children in their first year of vaccination.^{537,1500,1502,2184} In the elderly, serum antibody responses are typically lower than in younger subjects,^{646,1364,1596} which spurred the development of a high-dose vaccine (containing 60 µg of HA per component) that is now available for adults 65 years of age and older.^{245,537,2001}

Whole virion vaccines are more immunogenic and cross-protective than subvirion vaccines,^{127,170,496,610,1224,1579,1673,1964,2269,2273} likely because the RNA content of whole virus preparations stimulates TLR7⁶¹⁰ (see Pathogen Recognition

Receptors section); however, due to their higher reactogenicity, they are not used widely.

Live attenuated vaccine viruses replicate primarily in epithelial cells of the nasopharyngeal mucosa where they induce mucosal IgA antibodies, serum IgG antibodies, and cellular immunity, overall stimulating better cross-protection than inactivated viruses^{30,106,107,356,544,773,2076,2129} (reviewed in²⁰⁸⁰). Compared to inactivated vaccines, vaccination with live attenuated vaccine more closely resembles a natural infection, stimulating both arms of the immune system and providing better heterosubtypic immunity.^{356,1519,1962}

The addition of adjuvants to seasonal vaccines [and to avian virus vaccines and A(H1N1)pdm09 vaccines] increases their immunogenicity, particularly in immunologically naïve individuals^{126,577,1524} [see also Vaccines to Avian Influenza Viruses and Vaccines to A(H1N1)pdm09 Virus sections].

Controlled studies comparing the antibody response after intradermal and parenteral administration of vaccine containing comparable amounts of HA antigen indicated that intradermal administration offers a dose-sparing advantage over parenteral administration.^{1117,1695,1696,2143} Such approaches may be particularly important in the face of a pandemic when estimates indicate that vaccine supply will be a rate-limiting step.

The duration of immunity after inactivated influenza vaccination has not been evaluated systematically, but a relatively rapid decline in antibody levels suggests that protective immunity is of short duration. At any rate, antigenic changes in the influenza virus predicate annual immunization with current vaccines.

Efficacy of Seasonal Influenza Vaccines

Vaccination with influenza A and B viruses reduces infection and influenza-related illness.^{50,472,523,921,1378,1422,1423} The timing of vaccination is important since protective levels of antibodies are usually not reached until 2 weeks after vaccination.^{177,1157}

For inactivated vaccines, the levels of neutralizing antibodies against the infecting strain correlate well with the level of protection.^{326,813,1499,1591,1674} For live attenuated vaccines, the hemagglutination inhibition antibody test is not an optimal correlate, as seroconversion rates often remain low,^{109,544,978,2086} and protection has been observed in the absence of significant levels of antibody responses.^{472,2089}

Vaccine efficacy, defined as the reduction of cell culture–confirmed influenza illness, ranges from 70% to 90% in years in which the vaccine strains closely match the circulating viruses, and 50% to 80% in years when the vaccine is not well matched.^{98,172,411,536,790,919,1515,1517,1553,1874,1977,2160} Several meta-analyses have clearly established the benefits of vaccination.^{790,920,1515,2160} In healthy adults, inactivated and live attenuated vaccines provide similar levels of protection.^{172,411,472,482,1514,1515,1553,1554,1977,2080,2089,2199}

In the elderly, vaccine efficacy is significantly lower than that in young adults,^{69,70,672,1769} ranging from 20% to 40% in years of good antigenic match, and little protection in years of poor antigenic match.^{335,903,1217,1413,1518,1552} Limited data suggest that live attenuated and inactivated vaccines are of similar efficacy in the elderly.^{650,2042}

In children, influenza vaccines are efficacious.^{105,108,164} In this age group, live attenuated vaccine is more efficacious than inactivated vaccine,^{45,103,539,919,1514,2080,2151} and also provides better protection against antigenically mismatched strains.^{106,571,728,729}

Compliance with the currently recommended two doses of vaccine for children may be low; however, several studies demonstrated that even a single dose of live attenuated vaccine elicits protective immune responses in more than half of the children tested.^{108,164,2033}

Vaccination protects the vaccine recipient, but unvaccinated individuals can also benefit if the extent of vaccination is sufficient to dampen the epidemic spread of virus in the community (herd effect).^{386,509,621,854,1039,1044,1411,1501,1653,2201,2238}

Vaccination of high-risk groups, including pregnant women,^{742,895,1230,1440,1505,2347} patients with impaired immunity due to cancer,^{191,348,524,1115,1253,1353,1580,1797,1849,1974,2330} organ transplants,^{9,133,134,148,173,242,455,492,597,769,1004,1040,1111,1115,1346,1354,1794,1913,2159} HIV infections,^{1043,1045,1115,1194,1225,1398,1498,2298} or patients with chronic heart disease^{392,1298} is efficacious, although the antibody responses may be lower than those in healthy individuals.

Recommendations for Seasonal Influenza Vaccines

Recommendations for vaccination in the United States have continued to expand. Currently, annual vaccination is recommended for all over 6 months of age.⁵³⁷ Protection of persons at higher risk for influenza-related complications should continue to be a focus of vaccination efforts as providers and programs transition to routine vaccination of all persons aged 6 months or older. A summary of current influenza vaccination recommendations follows (modified after⁵³⁷):

When vaccine supply is limited, vaccination efforts should focus on delivering vaccination to person who:

- Are aged 6 months to 4 years (59 months)
- Are aged ≥50 years
- Have chronic pulmonary (including asthma), cardiovascular (except hypertension), renal, hepatic, neurologic, hematologic, or metabolic disorder (including diabetes mellitus)
- Are immunosuppressed (including immunosuppression caused by medications or by human immunodeficiency virus)
- Are or will be pregnant during the influenza season
- Are aged 6 months to 18 years and receiving long-term aspirin therapy and who therefore might be at risk for experiencing Reye syndrome after influenza virus infection
- Are residents of nursing homes and other chronic-care facilities
- Are American Indians/Alaska Natives
- Are morbidly obese (body mass index ≥ 40)
- Are health-care personnel
- Are household contacts and caregivers of children aged less than 5 years and adults aged 50 years or older, with particular emphasis on vaccinating contacts of children aged <6 months
- Are household contacts and caregivers of persons with medical conditions that put them at higher risk for severe complications from influenza

Vaccines to A(H1N1)pdm09 Virus

Based on the initial characterization of A(H1N1)pdm2009 viruses, the WHO recommended a vaccine strain (A/California/07/2009) on May 26, 2009 (http://www.who.int/csr/resources/publications/swineflu/H1N1Vaccinevirus_recommendation26May2009.pdf). Early studies indicated that the

candidate vaccines grew poorly in eggs (<http://www.thelancet.com/H1N1-flu/egmn/0c03c805>), and that two doses of vaccine might be needed to elicit protection against the novel virus.^{439,1071} However, several egg- and cell culture-grown, inactivated and live attenuated vaccines became available that grew to reasonable titers and, more importantly, triggered robust immune responses after one vaccination^{254,324,666,1215,1535,1664,1751,2122,2124,2249,2376} (for an overview of clinical trials, see⁶²⁷). Overall, seroconversion rates were lower in children,^{1215,1664,2376} although one dose of vaccine induced protective immune responses in some children.¹⁵³⁵ The robust immune responses in adults likely resulted from partial immunity due to prior infection with an antigenically similar strain (see The H1N1 Pandemic in 2009 section); in the United States, vaccination with the 1976 swine H1N1 virus also contributed to partial immunity to the A(H1N1)pdm09 virus.^{982,1361}

Vaccines against A(H1N1)pdm09 virus became available in China, Europe, Australia, and the United States in the fall of 2009^{251,254,933,1975} (<http://www.ema.europa.eu/influenza/vaccines/home.htm>; <http://www.tga.gov.au/alerts/medicines/h1n1vaccine.htm>). By February 2010, about 30 A(H1N1)pdm09 vaccines had been approved.⁶²⁷ In the United States, nonadjuvanted subvirion vaccines and a live attenuated vaccine were available; one dose was recommended for adults, and two doses for children between the age of 6 months and 9 years. In Europe, only inactivated (whole virus and subvirion) vaccines have been approved, and two doses are recommended for all age groups; both nonadjuvanted vaccines and preparations adjuvanted with MF-59 or ASO3 received market authorization. MF-59 greatly enhanced the responses to A(H1N1)pdm09³²⁴ and HPAI H5N1¹⁹⁶⁰ vaccines. A similar dose-sparing and enhanced response to novel antigens has been seen with ASO3 in adults² and children.²³³

The safety of the A(H1N1)pdm09 vaccines has been monitored closely, particularly for cases of GBS (see Reactogenicity of Seasonal Influenza Vaccines section). While a few cases of GBS have been reported after vaccination with A(H1N1)pdm09 vaccines,⁸⁴⁵ the frequency of reported GBS cases does not exceed the baseline number of cases reported annually (http://vaers.hhs.gov/resources/2010H1N1Summary_June03.pdf).

Vaccines to Avian Influenza Viruses

For most vaccines to highly pathogenic avian influenza viruses, the multibasic cleavage site in the HA protein is replaced with a low-pathogenic motif^{834,837,1525,1992,2207} (see HA Cleavage section) to generate attenuated vaccine viruses. This step is critical to increase the biosafety of vaccine production, and to avoid low vaccine virus yields in eggs resulting from the killing of the chicken embryo by the highly pathogenic avian viruses.

The first clinical trials of vaccines to HPAI H5N1 viruses indicated that very high amounts of antigen²⁰⁸⁷ and/or two doses of antigen, possibly in combination with adjuvant,¹⁷⁰ may be required to elicit protective immune responses. Since then, a number of candidate vaccines have been tested in clinical trials, including inactivated whole virus vaccines,^{478,479,521,862,1224,2020,2121,2123,2275,2276} inactivated subvirion vaccines,^{63,96,104,117,124,167,309,312,313,422,777,840,1007,1008,1144,1188-1190,1193,1466,1537,1617,1761,1765,1826,1905,2153,2275,2276,2350} and live attenuated viruses.^{978,1761} Most of these candidate vaccines were

grown in eggs; however, several were propagated in Vero,⁴⁷⁹ MDCK,¹⁰⁰⁷ or primary monkey kidney cells.⁷⁶⁶ In addition, a DNA vaccine,¹⁹⁰⁵ virus-like particle vaccine (<http://www.medicalnewstoday.com/articles/139352.php>), and vaccines composed of recombinant M2 protein expressed in *Escherichia coli* (http://www.who.int/vaccine_research/immunogenicity/immunogenicity_table.xls2009), or recombinant HA protein expressed in insect cells,^{766,2093} have been tested in clinical trials. For an overview of clinical trials, see http://www.who.int/vaccine_research/diseases/influenza/flu_trials_tables/en/ (last modified: 06/08/2010; accessed 05/30/2011).

These studies tested various virus strains, vaccine preparations, and vaccination regimens, including different amounts of antigen administered in one to three doses at different intervals, with or without adjuvants. Generally, nonadjuvanted vaccines are of low antigenicity in humans^{124,167,170,309,1008,1189,1193,1311,2087}; the addition of aluminum salts as adjuvants (currently the only adjuvant approved in the United States for use in influenza vaccines) provided little or no increase in immunogenicity,^{124,170,1009,1189,1190,1311} whereas oil-in-water emulsions such as MF-59 (approved in Europe for use with inactivated vaccines) and ASO3 [approved in Europe for use with A(H1N1)pdm09 vaccine] increased the immunogenicity of experimental H5N1 vaccines more noticeably.^{63,124,1189,1193,1311,1765} By 2010, several egg-derived, inactivated H5N1 influenza vaccines had been approved in different countries, including four whole virus vaccines adjuvanted with aluminum and one split virus vaccine adjuvanted with ASO3 (reviewed in¹⁶⁷⁹).

Other vaccine approaches are in different stages of development. These include inactivated low-pathogenic surrogate H5N3^{576,1269,1524,1960,1963} or H5N4^{1240,2022} virus; H5 HA or NP protein expressed by baculovirus,^{641,2090,2093} adenovirus,^{594,820-822,828,1616,1706,2132,2149} alphavirus,^{847,1823} poxviruses,^{24,967,1097,1098,1122,1349,1669,1691,1692,1732,1954} or Newcastle disease virus.^{423,424} Virus-like particles generated by expressing the influenza virus HA, NA, M1, and/or M2 proteins have been tested,^{42,174,365,368,425,766,768,962-964,1142,1299,1638,1917,2016,2039,2274} and a VLP vaccine is now in clinical trials (<http://www.medicalnewstoday.com/articles/139352.php>). DNA vaccines to H5 HA, NP, NA, and/or M2^{270,286,287,425,502,505,743,1038,1076,1126,1128,1281,1604,1706,2079,2284,2312} have been tested, but often suffered from suboptimal immune responses; however, several DNA vaccines are now in clinical trials.^{447,928,937,1905} Delivery of a DNA construct by small-particle aerosol has proven highly immunogenic in nonhuman primates.¹⁹¹⁸

The rapid evolution of HPAI H5N1 viruses might result in suboptimal cross-protection against viruses from different clades, and several H5N1 vaccines may have to be prepared to cover the currently circulating clades (for an overview of recently circulating clades and their antigenic properties, and an overview of current candidate vaccines, see http://www.who.int/csr/disease/avian_influenza/guidelines/2011_02_h5_h9_vaccinevirusupdate.pdf). However, recent data indicate that vaccination with an antigenically distinct H5N1 vaccine has a priming effect that leads to a faster and stronger response upon revaccination.^{576,1965} Hence, prepandemic priming,⁹²² potentially limited to high-risk groups, may be considered to prepare for a possible H5N1 pandemic.

Similar vaccine strategies are being applied to viruses of the H7^{358,405,906,925,943,944,1392,1608,1611,2016,2078,2242} and H9 subtypes.^{47,211,775,977,1684,1685,1964} Clinical trials have been conducted

for live attenuated H7N3²⁰³⁰ and H9N2⁹⁷⁷ viruses. A cell culture-grown H7N1 split virus vaccine,³⁵⁷ and H9N2 whole virus and subunit vaccines¹⁹⁶⁴ have also been evaluated.

Universal Vaccines and Other Approaches to Influenza Vaccination

Universal influenza A vaccines that protect against viruses of all subtypes are highly desirable. Antibodies against the highly conserved ectodomain of the M2 ion channel protein are broadly cross-reactive (see Humoral Immunity section), but a DNA/adenovirus vaccine expressing M2 is suboptimal in ferrets.¹⁷⁰⁶ A vaccine in which the M2 ectodomain is expressed as a fusion peptide of the hepatitis B virus core protein is now in clinical trials.^{531,1816} Broadly neutralizing antibodies to a conserved region in HA2 (see Humoral Immunity section) are attractive as broad-acting therapeutics, while the HA2 stalk region may be an attractive vaccine candidate because of its broad protective efficacy.^{1953,2194} These approaches have not been tested yet in clinical trials. In another approach, a universal vaccine composed of a synthetic protein encoding conserved linear epitopes from the HA, NP, and M1 proteins is undergoing trials in humans.¹¹³ Other approaches to improving our current influenza vaccines include changes in the substrate for vaccine preparation, vector-based vaccines, DNA vaccines, recombinant proteins, virus-like particles (VLPs) and newer adjuvants (see review in¹¹³⁵).

PERSPECTIVES

Over the last decade, we have witnessed several important developments in influenza virology. Highly pathogenic avian influenza viruses, which in the past caused transient, local outbreaks, have now become enzootic in parts of Asia in the form of H5N1 viruses. It is unlikely that these viruses will be eradicated in the near future. More likely, they will continue to circulate in—and transmit between—wild bird and domestic poultry populations, with ample opportunity for reassortment with other avian influenza viruses. In 2007 to 2008, oseltamivir-resistant H1N1 viruses became dominant around the world. This event reminds us that novel antiviral compounds, ideally targeted at different viral proteins and/or steps in the viral life cycle, are urgently needed. Finally, the H1N1 pandemic in 2009 caught most researchers by surprise, since the next pandemic was believed to be caused by a virus of an HA subtype that is not circulating in humans. Hence, while the next pandemic was thought to be caused by a virus of the H5, H7, or H9 subtype (scenarios that should not be dismissed), the H1N1 pandemic in 2009 has renewed the awareness for the pandemic potential of H1, H2, and H3 viruses. In particular, H2 viruses, which have not circulated in humans since 1968, are now receiving more attention.

Techniques are in place to rapidly sequence, analyze, generate, and test novel influenza virus strains and potential vaccine candidates. The development of additional adjuvants and the transition to cell culture systems for vaccine production will provide more flexibility for scale-up in case of a pandemic. However, significant administrative and regulatory challenges in the development of novel vaccines and antivirals remain.

In summary, the most important lesson may be that influenza pandemics do occur, will continue to occur, and will continue to challenge our ability to respond.

HISTORY

The family *Bunyaviridae* takes its name from Bunyamwera virus (BUNV), which was isolated originally from *Aedes* mosquitoes in the Semliki Forest, Uganda, during a yellow fever study in 1943.⁴⁹⁹ Following the isolation of BUNV, several additional arboviruses were discovered that clearly did not fit into the classic arbovirus group A and B antigenic groups (which now are included in the *Flaviviridae* family or the *Alphavirus* genus of the *Togaviridae* family) and were assigned to what became known as group C arboviruses.⁸³ During the next decade, further virus discovery and detailed serologic studies, together with biochemical and morphologic analyses,³⁶³ led to the concept of a Bunyamwera supergroup consisting of groups of viruses that could be linked by repeatable serologic cross-reactions. Serogroups (viruses related by their reactivity in any serologic test) and complexes (closely related members of a serogroup) were further defined for these viruses.⁷³

The family *Bunyaviridae* was formally established in 1975.⁴²³ The International Committee on Taxonomy of Viruses (ICTV) approved the creation of the *Bunyavirus* genus in 1980, along with viruses morphologically and biochemically similar but antigenically distinct, that formed the *Uukuvirus*, *Phlebovirus*, and *Nairovirus* genera.⁴⁶ The discovery of a novel group of rodent-borne viruses and another group of plant infecting viruses with conforming molecular properties respectively led to the additions of the *Hantavirus* genus in 1985, and the *Tospovirus* genus in 1991. Further studies demonstrated a close biochemical similarity between uukuviruses and phleboviruses, resulting in their combination into the *Phlebovirus* genus in 1991.⁷¹ To prevent confusion when discussing viruses in the *Bunyavirus* genus as opposed to the family as a whole, the former was renamed *Orthobunyavirus* in 1995.¹⁴² Viruses within each genus are thus referred to as hantaviruses, nairoviruses, orthobunyaviruses, and so on, whereas the term “bunyavirus” is used to refer to any member of the family. Currently more than 350 named viruses are included in the family, making it one of the largest families of RNA viruses.

Except for the hantaviruses, which are transmitted in aerosolized rodent excreta, bunyaviruses are carried and

FIGURE 42.1. Schematic of a bunyavirus virion. The three genome segments (L, M, and S) are encapsidated by nucleocapsid protein to form ribonucleoprotein complexes (RNPs), and together with the viral L protein (RNA dependent RNA polymerase, RdRp) are packaged within a host cell–derived lipid envelope modified by insertion of the viral glycoproteins Gn and Gc. Note that there is no matrix protein.

transmitted by arthropods, primarily mosquitoes, ticks, sand flies, or thrips.

BUNV is the prototype of the family, and remains an important research model. It was the first bunyavirus whose genome was completely sequenced,^{141,306} and significantly was the first segmented genome negative-sense RNA virus that was recovered (rescued) entirely from cloned complementary DNA (cDNA).^{62,450}

CLASSIFICATION

The essential criteria for inclusion in the family are enveloped virions of 80 to 120 nm diameter (Fig. 42.1), containing a tripartite, single-stranded RNA genome of negative- or ambi-sense polarity, which replicate in the cytoplasm, and usually assemble at the Golgi complex. Assignment to one of the five genera is based on lack of serologic cross-reactivity with members of other genera, the patterns of sizes of virion proteins (Table 42.2) and genome segments (Table 42.1), gene expression strategy (Fig. 42.2), and conserved terminal nucleotide sequences of the genomic RNAs (Table 42.3). The ICTV, through the *Bunyaviridae* Study Group, describes criteria for the designation of individual species within each genus.³⁷² These designations, which are based on rather limited molecular data, should be treated with caution and as being fluid. The field requires large-scale, organized sequencing projects to more accurately understand the

relationships between these viruses, and in particular to investigate the extent of genome segment reassortment among isolated viruses.^{65,378,390,391} A potential prototype of a sixth genus, Gouleako virus, has recently been described.³²⁹ This virus is most similar to phleboviruses but appears restricted to mosquitoes and could not infect vertebrate cells in culture. Table 42.4 lists the most notable members in the currently defined genera, and a brief introduction to each genus follows.

Orthobunyavirus Genus

The largest genus of bunyaviruses is the *Orthobunyavirus* genus, which contains more than 170 named viruses that are found throughout the world. Almost all of these viruses are transmitted by mosquitoes and have amplification cycles in a variety of vertebrate hosts.^{73,372} Among important orthobunyavirus pathogens in humans are La Crosse virus (LACV) that causes pediatric encephalitis, Oropouche virus (OROV) that causes a debilitating febrile illness, and Ngari virus that causes hemorrhagic fever, whereas Aino, Akabane, and Cache Valley viruses are examples of viruses causing disease in domestic animals (Table 42.4).

Classification of orthobunyaviruses has proven to be a complex issue. The majority of viruses have been placed in one of 18 serogroups based on serologic relatedness of complement fixing antibodies (mediated by the N protein) and hemagglutinating and neutralizing antibodies (mediated by the glycoproteins), although a number of viruses classified into the *Orthobunyavirus* genus are currently not assigned to any of these serogroups.^{73,372} The 18 serogroups are Anopheles A, Anopheles B, Bakau, Bunyamwera, Bwamba, Group C, Capim, California, Gamboa, Guama, Koongol, Minatitlan, Nyando, Olifanstlei, Patois, Simbu, Tete, and Turlock. Serologic relatedness varies within a serogroup and is further complicated by the occurrence of natural reassortant viruses (e-Fig. 42.1), such that viruses may be more related to members of one group or another depending on the assay used.⁷²

The latest report of the ICTV delineates the orthobunyaviruses into 44 species,³⁷² although as described above such classification should be regarded as fluid because of the paucity of molecular data. Comprehensive molecular genetic studies have involved viruses in only 4 serogroups, namely Bunyamwera, Group C, California, and Simbu,^{57,126,378,457} but S segment nucleotide sequences have been obtained for one or two representatives of the Anopheles A, Anopheles B, Bakau, Bwamba, Nyando, Tete, and Turlock serogroups.^{292,351,588} In most cases the S genome segment encodes two proteins, N and, in an overlapping reading frame, a small nonstructural protein termed NSs. N and NSs proteins are translated from the same

viral messenger RNA (mRNA) species as the result of alternate AUG-initiation codon selection.^{48,144} However, viruses in the Anopheles A, Anopheles B, and Tete serogroups do not show evidence of having an NSs ORF. In addition, these viruses have rather longer N proteins than those in the other serogroups.³⁵¹

Phlebovirus Genus

The *Phlebovirus* genus contains more than 80 viruses, with about half classified into nine antigenic complexes that are regarded as species, whereas 33 are considered as tentative species in the genus. The viruses of the genus *Phlebovirus* are present throughout the world, with the exception of Australia, and are more diverse in terms of arthropod vector than those of the other arthropod-borne genera. Most virus members are associated with phlebotomine sandflies, hence the genus name *Phlebovirus* (see Table 42.4). However, there are prominent exceptions, such as Rift Valley fever virus (RVFV), a medically and agriculturally important virus in Africa, which is primarily associated with *Aedes* species mosquitoes. In addition, Uukuniemi virus (UUKV), which has been used in a number of laboratory studies, is associated with the tick *Ixodes ricinus*. Recently a newly emerged phlebovirus was described in China (Huaiyangshan virus or severe fever with thrombocytopenia syndrome virus) that is associated with significant human mortality, and is transmitted by *Haemaphysalis* ticks.⁵⁹⁵

RVFV was first isolated in 1930 by Daubney et al. from an infected newborn lamb as part of an investigation of a large epizootic of disease causing abortion and high mortality in sheep.¹¹³ Large RVFV epizootics in various areas of sub-Saharan Africa have been noted since that time, and clinically compatible outbreaks have been retrospectively identified as far back as 1912.¹³³ Several decades passed before serologic and molecular similarities to phlebotomine fever viruses were noted. Sandfly fever Sicilian and Naples viruses (SFSV, SFNV)

were first isolated from American troops with febrile illness in the Palermo region of Sicily, Italy in 1943 and Naples, Italy in 1944, respectively, by inoculation of acute-phase sera into human volunteers and passage in newborn mice.⁴⁵⁶ Outbreaks of compatible human illness in the Mediterranean region date back to the time of the Napoleonic Wars, and association of the disease with sandflies was suggested as early as 1905.²⁰³

Nairovirus Genus

The nairoviruses are almost exclusively tick-borne viruses, although a few isolations have been made from *Culicoides* flies and mosquitoes (Table 42.4). Several serogroups exist, but the most important ones are the Crimean-Congo hemorrhagic fever (CCHF) group, which includes CCHF virus (CCHFV) and Hazara virus, and the Nairobi sheep disease (NSD) group, which includes NSD virus (NSDV) and Dugbe virus (DUGV).

The *Nairovirus* genus was named after NSDV, which was originally isolated in Nairobi, Kenya in 1910 by inoculation of sheep with the blood of sheep with acute gastroenteritis.³⁵⁴ The virus is now known to be present throughout various parts of Africa, and possibly India. CCHF was first recognized in the Crimean peninsula in the mid-1940s, when a large outbreak of severe hemorrhagic fever among agricultural workers was identified. The outbreak included more than 200 cases and a case fatality of about 10%.⁹⁹ Similar disease cases were later reported throughout the European and central Asian republics of the former Soviet Union, Romania, and Bulgaria. However, the virus was first isolated from a patient with a one-day fever in Kisangani, Democratic Republic of Congo, in 1956.⁴⁹⁴ It was some years before the connection was established, but subsequent serologic studies and virus isolations from Asia and Europe revealed that the viruses from the different outbreaks and geographic regions were essentially the same virus, which then became named CCHFV.^{82,100}

Hantavirus Genus

The discovery of hantaviruses traces back to 1951 to 1953, when United Nations troops were deployed during the border conflict between North and South Korea. More than 3,000 cases of an acute febrile illness were seen among the troops, about one third of which exhibited hemorrhagic manifestations, and an overall mortality of 5% to 10% was seen.^{129,305} The disease was initially termed Korean hemorrhagic fever but is now referred to as hemorrhagic fever with renal syndrome (HFRS). Despite considerable efforts, it took about 25 years until the field mouse, *Apodemus agrarius*, was identified as the rodent reservoir, and the virus was eventually isolated. At that

NA, North America; SA, South America; N.D., not determined.

time, all identified viruses of the family *Bunyaviridae* were known to be arthropod-borne viruses. Therefore, it was a big surprise when this rodent-borne virus was shown to share characteristics of viruses of the family *Bunyaviridae*. The virus was named Hantaan virus (HTNV), after the Hantaan river close to the location of some of the initial Korean cases, and became the prototype of the *Hantavirus* genus.³⁰⁵

During the course of the early studies in Korea, it became clear that HFRS cases were also occurring in urban areas. Years of investigation finally demonstrated that the urban cases in Korea, China, and Japan were associated with infection with Seoul virus, which is hosted by the rats *Rattus norvegicus* and *R. rattus*.^{300,305,514} For more than 50 years, a similar, but generally milder, disease termed nephropathia epidemica (NE) was

described in various parts of Scandinavia.³⁷⁵ Following the isolation of HTNV, the virus was shown to react with sera from patients with convalescent phase NE.³⁷⁵ This led to the discovery of Puumala virus (PUUV) as the cause of this form of HFRS and the bank vole, *Clethrionomys glareolus*, as the virus host.

The most recent major event in the history of hantaviruses was the discovery of hantavirus pulmonary syndrome (HPS) in the southwestern United States in 1993.³⁷³ A cluster of cases was identified in the Four Corners region, which presented with a flu-like illness (i.e., fever, headache, muscle aches, chills, and so on), but rapidly progressed to a more severe respiratory disease with bilateral pulmonary infiltrates, respiratory failure, shock, and death, occurring approximately 2 to 10 days after onset of illness in almost 50% of the cases.²⁵⁷ Within a couple of weeks of the initial outbreak, a newly identified virus, Sin Nombre virus (SNV), was shown to be the cause of HPS, and the rodent reservoir was shown to be the common deer mouse, *Peromyscus maniculatus*.^{96,373} Within the next several years, HPS was shown to occur throughout the Americas from Canada to Patagonia, and was found to be caused by at least 10 hantaviruses, each associated with a different rodent species. During the study of the hantaviruses associated with HPS and HFRS, many additional hantaviruses not known to be associated with human illness were discovered in a wide variety of rodent hosts (Table 42.4).

In addition to rodents, a number of hantaviruses have been isolated from insectivores. In fact the first hantavirus isolated was Thottapalayam virus, from the Asian house shrew, in Southern India,⁷⁹ although it was not recognized as a hantavirus until several years later.⁵⁹⁴ Very recently a number of other insectivore-associated hantaviruses have been identified; interestingly, prevalence in these animals is much higher than in rodents. The insectivore-borne viruses are widely distributed across the globe and display greater genetic diversity than the rodent-borne hantaviruses.⁴³⁴

Tospovirus Genus

The tospoviruses are plant viruses that are transmitted propagatively by thrips.⁵⁷⁹ At least 13 species of thrips, in the

Frankliniella and *Thrips* genera, are reported to transmit these viruses.^{384,575} Several of these viruses are now recognized as being of significant agricultural importance.⁴²⁷

The history of the tospoviruses goes back to 1915, with the recognition of spotted wilt of tomatoes in Australia,⁶⁶ and then the subsequent isolation in 1930 of tomato spotted wilt virus (TSWV),⁴⁶⁰ from which the genus gained its name.²⁷⁵ By the late 1940s, TSWV infections were greatly reduced in the United States and Western Europe due to pesticide use controlling the onion thrips, *Thrips tabaci*, which was likely the primary vector at that time. The geographic spread during the 1960s and 1970s of the Western flower thrips, *Frankliniella occidentalis*, another efficient vector of TSWV, led to a rapid expansion of TSWV.^{543,575} The virus is now known to be global in distribution, and it is found throughout agricultural areas in warmer climate zones and prevalent in greenhouse cultivations in more temperate areas. In contrast to the other genus members, TSWV has an unusually wide host range, with more than 925 plant species, including 82 botanical families, reported to be susceptible to infection. These include several important crops such as peanuts, peppers, tobacco, potatoes, peas, tomatoes, celery, lettuce, and ornamental flowers, with crop losses amounting to more than a billion dollars.³⁹³ There are 21 viruses assigned to the *Tospovirus* genus, with currently eight recognized species.^{200,372}

VIRION STRUCTURE

Morphology

Under the electron microscope, negatively stained bunyaviruses appear spherical or pleomorphic, 80 to 120 nm in diameter, and display surface glycoprotein (GP) projections of 5 to 10 nm, which are embedded in a lipid bilayered envelope approximately 5 to 7 nm thick. (Fig. 42.3). With use of cryoelectron microscopic techniques, which more accurately preserve particle integrity, LACV particles were reported to be 75 to 115 nm in diameter,⁵²² whereas particles of RVFV and Uukuniemi

FIGURE 42.3. Morphology of bunyaviruses. **A:** Electron micrograph of glutaraldehyde fixed negatively stained Hantaan virions (*Hantavirus* genus). The morphologic units on the surface form a grid-like pattern. As described in the text, viruses in other genera show different surface characteristics. **B:** Thin-section electron micrograph of Puumala virus (*Hantavirus* genus). The interior of the virion has a filamentous or coiled bead appearance, presumably due to the presence of the ribonucleoprotein complexes (RNPs). **C:** Cryoelectron micrographs of purified vitrified-hydrated La Crosse virions (*Orthobunyavirus* genus). The glycoprotein spikes are clearly visible. (**A** and **B**, courtesy of Geisbert T, Kuhl K, White JS, U.S. Army Medical Research Institute of Infectious Diseases, Frederick, MD; **C**, courtesy of Prasad BVV, Baylor College of Medicine, Houston, TX.)

(UUKV) phleboviruses had mean diameters of 100 nm and 125 nm, respectively,^{162,386} and Tula and Hantaan hantaviruses had mean diameters of 130 to 135 nm.^{35,216} The spikes are thought to mostly consist of heterodimers of the two viral GPs, and biochemical analysis of purified LACV particles indicated that the two GP species were equimolar and present at about 650 copies per virion. The GPs interact to form surface morphologic units that vary among viruses in different genera.³³³ Virions in the *Orthobunyavirus* genus have surfaces covered with closely packed, knoblike morphologic units with no detectable order. Similarly, no obvious order was found for the small surface structures with central cavities observed on viruses in the *Nairovirus* genus.³³³ The appearances of viruses in the *Tospovirus* genus have been likened to that of the nairoviruses.³⁴⁴ Other than the presence of GP projections, which are observed as a fringe on negatively stained virions, distinctive surface structure has not been noted for these viruses.

Viruses in the *Phlebovirus* genus have round, closely packed morphologic units, approximately 10 to 11 nm in diameter, with central cavities approximately 5 nm in diameter.³³³ Negative staining of glutaraldehyde-fixed particles, freeze-etching techniques, and/or cryoelectron tomography demonstrated that the glycoprotein spikes of UUKV and RVFV are organized on a T-12 icosahedral lattice, an arrangement so far unique to phleboviruses.^{162,386,557} For UUKV, two pH-dependent conformations of the glycoproteins were observed: tall spikes at pH7 and flat spikes at pH6. It is suggested that at low pH the conformational change exposes hydrophobic regions on the GP, possibly on Gc, that facilitate fusion between the viral and endosomal membrane during viral entry,³⁸⁶ a mechanism observed for other enveloped viruses that enter cells via the endocytic pathway.

The surface structure of viruses in the *Hantavirus* genus also are distinctly ordered but have a square grid-like appearance (Fig. 42.3).⁵⁷¹ Electron cryotomography^{35,216} confirms that the Gn-Gc spike complex has fourfold symmetry. Each spike is likely composed of four Gn-Gc heterodimers that form lattices on the virion surface. Specific lateral interactions between spike complexes are thought to induce membrane curvature during the budding process.

The interior of virions, as observed by thin-section electron microscopy, has a filamentous or coiled bead appearance, presumably due to the presence of the ribonucleocapsids (Fig. 42.3).¹²² From single particle reconstructions of tomograms, internally virions contained parallel thread or rod-like structures assumed to be ribonucleoprotein complex (RNP); some were located very close to the membrane suggesting interaction with the cytoplasmic tails of one or both of the glycoproteins.^{35,216,386,440}

Biochemical and Biophysical Properties

The composition and structure of virions has been inferred from biochemical and morphologic studies. An overall chemical content of 2% RNA, 58% protein, 33% lipid, and 7% carbohydrate was estimated for UUKV.³⁸⁰ Sedimentation coefficients of virions range from 400 to 500 S, and their buoyant densities in sucrose are 1.16 to 1.18 g/cm³, and in CsCl, 1.20 to 1.21 g/cm³. Treatment with lipid solvents or nonionic detergents removes the viral envelope and results in loss of infectivity for arthropods and mammals.³⁸⁰ For plants, the envelope is not required for infectivity, as demonstrated in studies with

TSWV, for which repeated mechanical passage among plants resulted in a defective virus that was unable to produce enveloped particles but was able to replicate in plant cells.¹¹⁶

GENOME STRUCTURE AND ORGANIZATION

Viral Genome

Virions contain three single-stranded RNA genome segments designated as large (L), medium (M), and small (S). All three RNA segments of a virus have the same complementary nucleotides at their 3' and 5' termini. The terminal nucleotide sequences are highly conserved among viruses within a genus, but differ from those of viruses in other genera (Table 42.3). Base-pairing of the terminal nucleotides is predicted to form stable panhandle structures and noncovalently closed circular RNAs. Direct support for base-pairing comes from electron microscopy of RNA extracted from virions, in which three sizes of circular RNAs were evident.²⁰⁴

The RNA segments are complexed with N to form individual L, M, and S nucleocapsids, which were generally assumed to have helical symmetry,³⁷⁹ but analysis of isolated RVFV nucleocapsids did not show this pattern but rather a string-like appearance.⁴⁴⁰ Nucleocapsids released by nonionic detergent treatment of virions often also appear as circular structures in electron micrographs,⁴¹¹ suggesting that the complementary RNAs can base-pair even when complexed with protein in an estimated ratio of 4% RNA to 96% protein.⁴³¹ This hypothesis is supported by data showing cross-linking of the ends of nucleocapsid-enclosed RNAs by treatment with psoralens, which are photoreactive, nucleic acid, cross-linking agents.⁴³¹

At least one each of the L, M, and S ribonucleocapsids must be contained in a virion for infectivity; however, equal numbers of nucleocapsids may not always be packaged in mature virions, as suggested by various reports of equimolar or nonequimolar ratios of L, M, and S RNAs.^{49,218} Unequal complements of the ribonucleocapsids may contribute to the size differences of virions observed by electron microscopy.^{35,522}

In addition to ribonucleocapsids containing virion-sense RNA (vRNA), certain viruses in the *Phlebovirus* and *Tospovirus* genera encapsidate small amounts of complementary sense (cRNA or antigenome). The phlebovirus UUKV was found to have S but not M segment cRNA, and the tospovirus TSWV had both M and S cRNAs in virions.^{274,491} For the orthobunyavirus, LACV, S segment cRNA was detected in virions synthesized in insect cells, but not in mammalian cells.⁴³¹ Interestingly, the phlebovirus RVFV encapsidated all three cRNA gene segments, and, as will be described later (see "S segment products"), at least one of the cRNA genes may have a role in early replication processes.²²⁵

Coding Strategies of Viral Genes

Both similarities and noteworthy differences in the coding strategies of viruses in the family *Bunyaviridae* are known. Viruses in each genus encode all structural proteins in their cRNA. Certain viruses also encode nonstructural proteins in their cRNA or in their vRNA. Therefore, some viruses in the family *Bunyaviridae* use only a negative-sense coding strategy and others use a combination of negative-sense and ambisense coding strategies (Fig. 42.2).

S Segment Strategies

Viruses in the *Orthobunyavirus* genus have smaller S segments than those of viruses in other genera (Table 42.1). Some orthobunyaviruses encode two polypeptides, the nucleocapsid protein (N) and a nonstructural protein (NSs), in ORFs in cRNA⁴⁸ (Fig. 42.2), whereas others only encode N protein.³⁵¹ The presence of NSs in virus-infected cells was demonstrated for several members of the genus.¹⁴⁰ Only one S segment mRNA species can be found in orthobunyavirus-infected cells⁸⁴; therefore, N and NSs are generated by alternative start codon recognition by ribosomes.^{126,144}

Hantaviruses andairoviruses encode larger N proteins than viruses in other genera, (Table 42.2, Fig. 42.2).^{332,470} Some hantaviruses (e.g., SNV, PUUV, Tula [TULV] and Prospect Hill [PHV] viruses), have ORFs within the N ORF, and an NSs protein has been detected in PUUV- and TULV-infected cells.²²⁷ No NSs protein has been detected inairovirus infected cells. Only one S-segment mRNA, similar in size to the coding region for N, was identified in hantavirus- orairovirus-infected cells, indicating that transcription termination occurs shortly after the translation stop codon.^{469,563} Certain hantaviruses (e.g., SNV) have long 3' noncoding regions (of greater than 700 nucleotides) containing numerous repeated sequences. These repeats may result from polymerase slippage on the vRNA template.⁵⁰⁵

The ambisense coding strategy of the S segments of phleboviruses and tospoviruses produces N from a subgenomic mRNA that is complementary to vRNA, and NSs from a subgenomic mRNA of the same polarity as vRNA (Fig. 42.2).^{118,220} Evidence that the mRNA for NSs is copied from cRNA (after genome replication) comes from time-course studies. For the phlebovirus UUKV, N was detected at 4 to 6 hours after infection, whereas NSs did not appear until 8 hours after infection.^{492,542} Likewise, the mRNA for NSs of the tospovirus TSWV was detected in infected plant cells 15 hours later than for N.⁵⁰⁷ In addition, studies with the phlebovirus Punta Toro virus (PTV) demonstrated that protein synthesis inhibitors arrest production of NSs mRNA, but not N mRNA.²²² These results suggest that protein synthesis must occur before the NSs mRNA can be made. In contrast, studies with the phlebovirus RVFV demonstrated the presence of cRNAs to all three RNA segments in purified virions. Moreover, mRNA for the NSs protein was detected as early as 20 minutes after infection, concomitant with the appearance of mRNA for N, suggesting that the ambisense-encoded NSs mRNA are transcribed from the incoming antiviral sense RNA.²²⁵

M Segment Strategies

Sizes of M segments range from ~3,600 nucleotides to ~4,900 nucleotides (Table 42.1). All bunyavirus M segments encode the two envelope GPs in a single ORF of cRNA (Fig. 42.2). Previous designations of G1 and G2, which were based on relative migration of the proteins in polyacrylamide gels, have been replaced by designations of Gn and Gc, referring to the amino-terminal or carboxy-terminal coding of the proteins.²⁹⁴ As described below, it is becoming increasingly clearer that the functions of the Gn and Gc proteins are conserved among the five genera.

Some viruses encode NSm proteins, and others do not. Except for the tospoviruses, which use an ambisense strategy to generate NSm from a subgenomic mRNA, a single mRNA,

nearly equivalent in size to the cRNA ORF has been detected in virus-infected cells. For tospoviruses, separate, subgenomic messages for the Gn-Gc precursor and for NSm were identified.^{273,295} NSm is readily detected in infected plants and is the only M segment nonstructural protein in the *Bunyaviridae* family to have a clearly defined role (i.e., it is a movement protein [see “M Segment Products,” below]). Another possible role for NSm for some viruses may be as a virulence factor. For example, a genetically engineered RVFV lacking NSm induced more extensive apoptosis than did one with NSm and the expression of NSm significantly inhibited the cleavage of caspase 8 and 9 induced by staurosporine, indicating that the NSm protein suppresses apoptosis.⁵⁸²

L Segment Strategies

The L segments of hantaviruses, orthobunyaviruses, and phleboviruses are of similar size, (~6,500 nucleotides), whereas those of tospoviruses andairoviruses are considerably larger (~9,000 and 12,000 nucleotides, respectively; Table 42.1). All L segments of viruses in the family use conventional negative-sense coding strategies (Fig. 42.2). For each L segment described thus far, there are fewer than 200 nucleotides of total noncoding information, and there is no evidence for additional coding regions in either the cRNA or vRNA.^{117,141,143,209,360,465}

STAGES OF REPLICATION

The principal stages of the replication process for viruses in the *Bunyaviridae* are illustrated in Figure 42.4 and are summarized in the following:

1. Attachment, mediated by an interaction of viral proteins and host receptors
2. Entry, by receptor-mediated endocytosis
3. Uncoating, by acidification of endocytic vesicles, and fusion of viral membranes with endosomal membranes
4. Primary transcription of viral-complementary mRNA species from genome templates using host-cell-derived primers and the virion-associated polymerase
5. Translation of L, M, and S mRNAs
 - co-translational cleavage of M-segment polyprotein and posttranslational cleavage of precursors for some viruses
 - dimerization of Gn and Gc in the endoplasmic reticulum (ER)
6. Membrane-associated RNA replication
 - synthesis and encapsidation of cRNA to serve as templates for vRNA or, for ambisense genes, templates for subgenomic mRNA
 - genome replication
7. Morphogenesis
 - localization of N in budding compartments
 - transport of dimerized Gn and Gc to the Golgi
 - glycosylation
 - acquisition of modified host membranes, generally by budding into the Golgi cisternae
8. Fusion of cytoplasmic vesicles containing viruses with the plasma membrane and release of mature virions
 - more rarely, some viruses in some cell types have been observed to bud directly from the host cell's plasma membrane

FIGURE 42.4. Replication cycle of viruses in the family *Bunyaviridae*. Steps in the replication cycle are the following: 1. Attachment, mediated by an interaction of viral proteins and host receptors; 2. Receptor-mediated endocytosis; 3. Uncoating, by acidification of endocytic vesicles, and fusion of viral membranes with endosomal membranes; 4. Primary transcription of viral-complementary messenger RNA (mRNA) species from genome templates using host-cell-derived primers and the virion-associated polymerase; 5. Translation of L, M, and S mRNAs, co-translational cleavage of the M-segment polypeptide, dimerization of Gn and Gc in the endoplasmic reticulum (ER); 6. Membrane-associated RNA replication, synthesis, and encapsidation of cRNA to serve as templates for vRNA or, for ambisense genes, templates for subgenomic mRNA, genome replication; 7. Morphogenesis including transport of the structural proteins to the Golgi, glycosylation of Gn and Gc, budding into the Golgi cisternae; 8. Migration of Golgi vesicles containing viruses to the cell surface, fusion of vesicular membranes with the plasma membrane, and release of infectious virions. Some viruses in some cell types can bud both into intracellular vesicles and also from the plasma membrane.

Attachment and Entry

Viral Attachment Proteins and Cellular Receptors

The mechanisms by which members of the family *Bunyaviridae* gain access to the host cell's cytoplasm appear similar to those reported for many other enveloped viruses. The first step involves an interaction between cell surface receptors and viral attachment proteins, Gn and/or Gc. The presence of neutralizing and hemagglutination-inhibiting sites on both the Gn and Gc proteins of phleboviruses and hantaviruses^{27,252} suggests that both proteins may be involved in attachment. Although it is possible that both are directly involved, it is more likely that both are required due to conformational requirements that depend on dimerization of Gn and Gc.

In general, Gc appears to be the primary attachment protein for orthobunyaviruses in mammalian cells, mosquito cells, and mosquitoes.^{193,261,515} Consistent with this view, expression of M-segment products of three orthobunyaviruses demonstrated that Gc, but not Gn, could effect attachment and entry when tested in a cell-to-cell fusion assay and a pseudotype transduction assay.⁴¹⁹ However, the amino terminal half of BUNV Gc ectodomain is not required for infection of cultured mammalian cells,⁴⁸³ and this region can be replaced by green fluorescent protein (GFP) allowing the creation of viable viruses expressing chimeric Gc-GFP in their virions.⁴⁸⁶

For tospoviruses, the envelope GPs are required only for infection of their arthropod vectors, as evidenced by the ability of envelope-deficient mutants to replicate in plants after

mechanical transmission, but their inability to infect thrips.⁴⁴⁵ In addition, analysis of reassortant viruses demonstrated that mutations that disrupted the Gn-Gc ORF of TSWV ablated transmissibility by thrips.⁴⁹⁵ These studies provide indirect evidence that the L-polymerase protein remains associated with ribonucleocapsids and is active despite the absence of intact virions.

Although there are no specific reports of Gc being the attachment protein of tospoviruses, functional homology to the Gc proteins of other bunyaviruses was proposed based on amino acid sequence homologies detected for iris yellow spot virus.¹⁰⁶ In contrast, however, a study with a soluble, truncated form of TSWV Gn expressed in baculoviruses showed binding of this protein to epithelial cells in the midguts of thrips, suggesting that Gn could mediate attachment in thrips.⁵⁷³ Similar results were reported earlier with the orthobunyavirus LACV, in that virions treated with a protease that cleaved Gc but not Gn exhibited increased binding to the insect vector midgut, but reduced binding to cultured mammalian or mosquito cells.³²⁴ Given that both of these systems use a Gn protein in the absence of Gc, it remains to be determined whether Gn functions for attachment when in its native conformation on virions.

Host cell receptors have not been identified for most viruses in the family; however, pathogenic and nonpathogenic hantaviruses were shown to use $\beta 3$ and $\beta 1$ integrins, respectively, to enter endothelial cells.¹⁷⁰ This finding was suggested to relate to pathogenesis, in that binding of hantaviruses to integrins might disrupt their ability to regulate cell-to-cell adhesion and result in the vascular permeability characteristic of hantaviral diseases.¹⁷¹ In addition, decay accelerating factor (DAF)/CD55 a glycosylphosphatidylinositol (GPI)-anchored protein, has been shown to mediate HTNV and PUUV entry across the apical membrane of polarized epithelial cells,²⁷⁷ and gC1qR/p32, a 32-kD glycoprotein that interacts with complement protein C1q, binds HTNV and mediates infection of cultured A549 lung cells.⁹⁸

Entry of the Viral Genome into the Host Cytoplasm

Shortly after attachment, viruses in the *Phlebovirus* and *Nairovirus* genera were observed in phagocytic vacuoles.^{145,455} This suggested a mode of viral entry similar to that first described for alphaviruses in which the virus is endocytosed in coated vesicles, and inhibitor studies have confirmed this to be so for the animal-infecting bunyaviruses. Orthobunyaviruses, hantaviruses, and nairoviruses enter by endocytosis into clathrin-coated pits,^{239,463,490} and HTNV proteins were shown to colocalize with clathrin in confocal immunofluorescence studies.²³⁹ In addition, CCHFV requires functional microtubules for infection.⁴⁸⁹ By contrast, entry of UUKV phlebovirus is predominately in a clathrin-independent manner, and viruses enter Rab5a+ early endosomes and subsequently Rab7+ and LAMP-1+ late endosomes.³²³ After endocytosis, acidification of the endocytic vesicles is thought to promote a conformational change in Gn and/or Gc that facilitates fusion of the viral and cellular membranes, thereby allowing the viral genome and polymerase access to the cytoplasm. Infection is blocked if cells were treated with ammonium chloride, which prevents acidification.^{229,419,463,484} Additional indirect support for membrane fusion as a mode of entry came from experiments demonstrating the ability of viruses in the family to mediate syncytia formation at low pH.^{153,183,229,383,419,484,574}

Computational studies revealed that the Gc proteins have characteristics similar to those of class II fusion proteins identified for viruses in the *Flaviviridae* and *Togaviridae* families.¹⁶⁹ Such proteins have internal fusion domains, as opposed to terminal domains found for the class I fusion proteins. Experimental support for this finding was obtained by demonstrating interaction of the fusion peptide postulated for the Gc protein of the hantavirus, Andes virus (ANDV), with artificial membranes.⁵³⁷ In addition, several lines of evidence indicate that the Gc of orthobunyaviruses is involved in membrane fusion. Protease sensitivity assays, detergent partitioning experiments, and antibody-binding studies suggest that Gc undergoes a conformational change at pH conditions where fusion is observed.¹⁸² Mutational analyses of a hydrophobic region (residues 1,066–1,087) of LACV Gc that is well conserved among different orthobunyaviruses¹⁰⁶ supported this notion,^{229,420} and the residues flanking the predicted fusion peptide in BUNV Gc (residues 1,058–1,079) were shown to be structurally critical for the conformational change in Gc that occurs during the fusion process.⁴⁸³ LACV Gc alone, however, when expressed from recombinant vaccinia viruses, could not cause cell fusion, suggesting that an association of the two GPs may be needed for membrane fusion,²²⁹ and mutations in the cytoplasmic tail of BUNV Gn severely affected membrane fusion indicating that Gn must also play an important role in the fusion process.⁴⁸⁴ Likewise for HTNV, both Gn and Gc were required to achieve surface expression and cell-to-cell fusion activity.³⁸³ Recombinant LACV carrying mutations in the Gc fusion peptide was impaired for growth in both mammalian and insect cells but were still neurotoxic to neuronal cells, implying that the fusion peptide is a determinate of neuroinvasiveness but not necessarily neurovirulence.⁵⁰¹

Transcription and Replication

After uncoating of viral genomes, primary transcription of negative-sense vRNA to mRNA is initiated by interaction of the virion-associated L protein, which is an RNA-dependent RNA polymerase (RdRp), and the three viral ribonucleocapsids.⁵⁵ Studies with hantavirus N protein suggest that N participates in transcription initiation by facilitating dissociation of the RNA panhandle and by subsequently remaining attached to the 5' terminus of the RNA, thereby freeing the 3' terminus for RdRp interactions. Furthermore, N was suggested to be important for replication by acting as an RNA chaperone and transiently and continuously unfolding the RNA to allow it to form more stable structures.³⁴⁷ A role for N in both transcription and replication is also evident by analysis of the behavior BUNV N proteins carrying specific mutations, either in a minigenome assay or in the context of virus infection.^{135,560} Four BUNV temperature sensitive mutants, carrying single amino acid substitutions in N, could be divided into two groups, those that were defective in antigenome synthesis but not mRNA transcription, and those that were replication defective but transcription competent, suggesting that different domains within N are associated with different RNA synthesis activities.¹³⁵ The mechanism by which residues in N modulate template activity requires elucidation; one possibility is that transcription and replication require different cellular cofactors that bind to distinct regions on the N protein.

Because only L and N are needed for RNA synthesis,¹²⁷ the location of these proteins must correlate with the site of RNA

synthesis. For nairoviruses and hantaviruses, N (or L and N) proteins were found to localize to the perinuclear region and to have a peripheral association with perinuclear membranes.²⁸³ In cells infected with a recombinant BUNV expressing an epitope-tagged L protein immunofluorescence microscopy showed L to have a punctate to reticular staining pattern, with concentration of staining in the perinuclear region, whereas cell fractionation studies showed L to be distributed in both cytosolic and microsomal fractions.⁴⁸¹ Together, these data suggest that bunyavirus RNA replication is membrane-associated, similar to that described for flaviviruses.

The L Protein

To mediate replication, the RdRp must affect numerous enzymatic functions. For primed synthesis of mRNA from genomic templates and nonprimed synthesis of vRNA from cRNA templates (as will be described), the RdRp performs endonuclease, transcriptase, replicase, and probably RNA helicase activities. Motifs common to polymerases in general are conserved in the bunyaviral RdRps, most notably a catalytic core motif.^{26,237,282,360} The N-terminal domain of orthobunyavirus L proteins contains a conserved PD-(D/E)xK amino acid nuclease motif and the isolated domain of LACV L exhibited nuclease activity *in vitro*; furthermore, bioinformatic analyses indicated that viruses in all the other *Bunyaviridae* genera contain a similar domain.⁴⁴² The nuclease domain of LACV bears structural similarities to that of the PA subunit of the influenza A virus polymerase, suggesting a common origin of the cap-snatching process of segmented negative sense viruses. None of the other functions has been definitively localized to a region of the RdRp gene or gene product; however, comparison of two nairovirus L proteins with functionally defined regions of other polymerases revealed potential helicase, topoisomerase, and gyrase coding regions as well as an N-terminal cysteine-protease motif typical of the ovarian tumor (OTU) protein superfamily and protease.²⁶² Biochemical and structural analyses demonstrate that in addition to the deubiquitinase activity as shown by cellular OTU proteases, the nairovirus OTU also targets ISG15 modification and thus enhances its role in overcoming host innate immune defenses.^{5,77,165,230} The OTU domain is not required for the RNA polymerase activity by CCHFV in a minigenome system.⁴³

Genome Promoters

The template for bunyavirus transcription and replication is not naked RNA but RNA in the form of ribonucleocapsid.^{127,319} The 3' and 5' nontranslated complementary nucleotides contain signals for both mRNA synthesis and antigenome synthesis, and thus are the genome promoters. For the phleboviruses RVFV and UUKV, the first 13 or the first 10 nucleotides, respectively, of the 3' end of the genome are sufficient for RNA synthesis activity.^{156,424}

For the orthobunyavirus BUNV, a minigenome reporter system was used to demonstrate that optimal transcription required exact complementarity at the 3' and 5' termini; however, one to three nucleotide deletions could be tolerated at the 3' terminus, but not the 5' terminus.²⁶⁸ Although sequence changes at several positions could be tolerated as long as complementarity was maintained, some changes did reduce transcription. Interestingly, mutagenesis experiments indicated that the single exception to complementarity (a U residue at 3' position 9)

was critical for transcription from the genomic promoter, whereas the corresponding 5' position 9 could be changed without influencing transcription.³³ Therefore, the mismatch itself is not important, but the nucleotide is. This nucleotide, however, does not have to be maintained for transcription activity of the antigenomic promoter.³³ Together, these data suggest that the structure of the panhandles is more important than the sequence, but that the sequence also plays a role in promoter strength and activity.

To further investigate promoter regions in an authentic replication system, S segments with shortened complementary termini were introduced into a BUNV reverse genetics system, and rescued viruses were screened to determine the minimal terminal complementary region needed for virus production.³²² The minimal 3' and 5' deletion mutant viable in this system maintained 29 of the 85 untranslated nucleotides on the 3' end and 112 of the 174 untranslated nucleotides on the 5' end, whereas those with shorter untranslated regions were not viable. Therefore, although only the complementary regions are needed for promoter activity *in vitro*, actual virus production also requires some of the unique sequences in the untranslated regions at the 3' and 5' termini of BUNV.³²²

The *in vivo* importance of intact termini was also suggested by a study in which terminally deleted RNAs were shown to accumulate during the establishment of persistent infections with the hantavirus, Seoul virus (SEOV). It was hypothesized that as deletions accrued, fewer replication-competent genomes were present, leading to a downregulation of the replication processes, and possibly to persistence.³⁴² Similar deletions were found on the termini of ANDV M and L, but not S genes, leading to a speculation that differences observed in the relative abundance of Gn and Gc compared to N could reflect down regulation of M-segment expression from genes without intact termini.³⁸⁹

Primed mRNA Synthesis (Cap Snatching)

Like influenza viruses, viruses in the family *Bunyaviridae* prime mRNA synthesis with capped oligonucleotides that are scavenged from host mRNAs (Fig. 42.5). Cleavage of the capped primers is accomplished by endonuclease activity found in virions and associated with the L protein.^{398,442} Unlike influenza viruses, which take primers from newly synthesized mRNAs in the host cell's nucleus, members of the *Bunyaviridae* family use primers cleaved from cytoplasmic host cell mRNAs. Evidence has been presented that the hantavirus N protein binds to the 5' cap of cellular mRNAs to protect them from cell-mediated degradation, and that N accumulates in cytoplasmic processing bodies (P bodies) where protected 5' caps are sequestered, and hence can serve as a pool of primers to initiate mRNA synthesis.³⁴⁶ A result of this mode of mRNA transcription is the presence of 5' terminal extensions of approximately 10 to 20 heterogeneous nucleotides that are not found in vRNA.⁴⁷ Studies using anticap antibodies to immunoselect mRNAs¹⁹² have provided direct proof for the presence of caps on the scavenged primers. Further evidence for capped extensions of mRNAs was provided by a study of tospoviruses, in which plants were co-infected with TSWV and with a positive-strand RNA virus (alfalfa mosaic virus). The tospovirus acquired 5' mRNA extensions with nucleotide sequences that matched those of the other virus with a preference for cleaving at an A residue.¹²⁵ It was suggested that this

FIGURE 42.5. Transcription and replication scheme of negative-sense bunyavirus genome segments. The genome RNA and the positive-sense complementary RNA known as the antigenome RNA are found only as ribonucleoprotein complexes and are encapsidated by N protein (●). The messenger RNA (mRNA) species contain host-derived primer sequences at their 5' ends (■) and are truncated at the 3' end relative to the virion RNA (vRNA) template; the mRNAs are neither polyadenylated nor encapsidated by N protein. The sequence at the 5' end of an orthobunyavirus mRNA is shown.

preference is due to a need for base-pairing at the ultimate U residue of the gene segments. Consistent with this, later studies indicated that double and triple base complementarity to nucleotides at the ends of the tospovirus gene segments were preferred, even more than the single complementary residue.⁵⁴⁵ Interestingly, it was also found that newly synthesized mRNAs can serve as cap donors *in vitro* for tospoviruses, suggesting a “resnatching” mechanism.⁵⁴⁴

Other viruses in the family also have nucleotide or nucleotide motif preferences for endonuclease cleavage of capped primers. These preferences vary among the genera, and sometimes among viruses within a genus. A preferred primer sequence, or a favored nucleotide at the site of cleavage due to a need for limited base pairing with the viral genome, appears to be a common feature of primed transcription for bunyaviruses. In one study, the 3'-terminal nucleotides of the scavenged host primers often were similar to the 5'-terminal viral nucleotides.²³⁸ It was proposed that after transcription of two or three nucleotides of the nascent mRNA, the viral polymerase might slip backward on the template before further elongation, resulting in a partial reiteration of the 5'-terminal sequence. An extension of this concept, termed “prime and realign,” was proposed for mRNA transcription of hantaviruses.¹⁶⁸ According to this model (e-Fig. 42.2), priming by host oligonucleotides with a terminal G residue would initiate transcription by aligning at the third nucleotide of the viral RNA template (C residue). After synthesis of a few oligonucleotides, the nascent RNA could realign by slipping backward two nucleotides on the repeated terminal sequences (AUCAUCAUC) (Table 42.3), such that the G becomes the first nucleotide of the nontemplated 5' extensions (e-Fig. 42.2). The frequent deletion of one or two of the triplet repeats in hantaviral mRNA supports this sort of slippage mechanism and suggests that sometimes the initial priming might start at the C residue of the third triplet in the conserved sequence rather than at the C of the second triplet.¹⁶⁸

Bunyavirus transcription is unique among negative-sense RNA viruses in that functional viral mRNA synthesis requires ongoing protein synthesis,^{31,400,430,432,433,553} a finding that at face value appears incompatible with the presence of a virion transcriptase. In the absence of protein synthesis, only short transcripts are produced *in vivo* and *in vitro*. If the *in vitro* reaction is supplemented with rabbit reticulocyte lysate, however, full-length RNAs are synthesized. The translational requirement is not at the level of mRNA initiation, but rather during elongation or, more precisely, to prevent the transcriptase from terminating prematurely. A model to account for these observations proposed that in the absence of ribosome binding and protein translation, the nascent mRNA chain and its template can base-pair, thereby preventing progression of the transcriptase enzyme.³⁷ Recently this model (e-Fig. 42.3) has been tested using BUNV model templates containing translational stop codons,³¹ and the results showed that translation of nascent mRNAs prevented transcription termination. Thus orthobunyaviruses couple transcription and translation, a feature commonly found in prokaryotes, but rare in eukaryotic cells.

Transcription Termination

For gene segments with simple negative-sense coding, synthesis of M- and S-segment mRNAs terminates about 40 to 100 nucleotides before the end of the genome RNA template.^{109,148,235,399} Although most other negative-strand RNA viruses use a stretch of nucleotides rich in U residues to signal transcription termination and polyadenylation, no such tract has been consistently identified for members of the family *Bunyaviridae*. This is supported by experimental evidence showing that bunyavirus mRNAs are not 3' polyadenylated,^{1,400,542} but many have the potential to form stem-loop structures that are probably involved in enhancing translation of viral mRNAs.^{53,551}

By using a reporter system that involved mutated S segments, the transcription termination signal for the orthobunyavirus BUNV was mapped to a 33-nucleotide region within the 5' nontranslated region of the S segment.³² Within this region, a 6-nucleotide motif, 3'-GUCGAC-5' was critical to transcription termination. In addition, changing the nucleotides in this transcription termination signal revealed a second downstream transcription termination signal, which had a 5-nucleotide motif, 3'-UGUCG'-5', that was also found within the 33-nucleotide region of the upstream site, and that partially overlapped the critical 6-nucleotide motif. The finding that there are no U-rich regions in the transcription termination signal of BUNV is consistent with the absence of poly-A tails on the mRNAs.

Comparison of these S-segment sequences with those of other orthobunyaviruses revealed a high degree of conservation, suggesting that similar motifs also function for transcription termination throughout the genus, at least for S segments. A motif similar to that on the BUNV S segment was observed within the BUNV L, but not the M segment.³² Experimental mapping of BUNV L and M mRNA termination sites has not been reported.

Analysis of the L mRNAs of SNV hantavirus²¹⁸ and RVFV and Toscana (TOSV) phleboviruses⁷ showed they were co-terminal with the L vRNA template, suggesting L mRNA synthesis terminates by run-off of the RNA template.

A U-rich motif was proposed as the site of termination for the M mRNA and a C-rich motif (CCCACCC) as termination site for the S mRNA of SNV hantavirus.²¹⁸ Fine mapping

of M-segment mRNA termination sites for three phleboviruses (RVFV, TOSV, and SFSV) showed that termination occurred immediately following a C-rich domain in the template at a conserved motif 3'-C₁₋₃ GUCG/A-5'.⁷ Although previously it was thought the C-rich region itself was involved in transcript termination,¹⁷⁸ deletion of this region in template RNA did not affect specific termination at the identified motif.⁷

The mechanism of transcription termination of the ambisense genes of phleboviruses and tospoviruses was initially thought to involve RNA secondary structure in the intergenic region.^{103,118,146,187,188,493} However, reanalysis of computer predictions of hairpin formation in these intergenic regions suggest that they are unlikely to form because of their complexity or low energy.⁷ Detailed mapping of mRNA termination sites for the N and NSs mRNA of RVFV, TOSV, and SFSV phleboviruses showed that the 3' ends of the mRNAs contained most of the intergenic sequence and indeed overlapped each other.⁷ Furthermore, termination occurred for both messages at the same motif, 3'-C₁₋₃GUCG/A-5', as in the M segment. Two copies of this motif are thus present, one in vRNA (genome) and one in the cRNA (antigenome). The conservation of this motif in viral genomes that display considerable sequence diversity suggests a similar mechanism for transcription-termination in the M and S segments. Deletion of either copy of the motif in RVFV S segment did not prevent correct termination of unaffected N or NSs mRNA, but the mutant viruses were attenuated in growth compared to wild-type.⁷

Genome Replication

The change from primary transcription to replication requires that the RdRp, either acting alone or in concert with undefined viral or cellular factors, must at some point, switch from primed mRNA synthesis to independently initiating transcription at the precise 3' end of the template to produce a full-length transcript. The processes involved in making that switch from primary transcription to genome replication have not been defined completely for any member of the family. Presumably, some viral or host factor is required to signal a suppression of the transcription termination signal responsible for generation of truncated mRNA and also to prevent the addition of the capped and methylated structures to the 5' termini of the cRNAs. There is no question that genome replication and subsequent secondary transcription are prevented by transla-

tional inhibitors such as cycloheximide. These results indicate that continuous protein synthesis is required for replication of the genome. Although not proven, it is likely that synthesis of N is required for genome replication, as described for other negative-strand RNA viruses such as the rhabdovirus, vesicular stomatitis virus, and the paramyxovirus Sendai virus. For these viruses, encapsidation by N seems to serve as an antitermination signal, thus allowing full-length genome synthesis.

A prime-and-realign model was also postulated for the nonprimed transcription of hantaviral vRNA and cRNA, except that transcription would initiate with pppG alignment at the third nucleotide (C residue) of the template RNA. After synthesis of several nucleotides, polymerase slipping would realign the nascent RNA such that the initial priming G residue would overhang the template. It was further theorized that nucleolytic activity of the L protein might remove the overhanging G, leaving a monophosphorylated U residue at the nascent 5' end. The presence of the monophosphorylated U on HTNV RNA was experimentally demonstrated¹⁶⁸ (e-Fig. 42.2).

Indirect evidence suggesting that a prime-and-realign method of initiation is used by phleboviruses was obtained by using a reconstituted transcription system to study the polymerase recognition sequence at the 3' termini of the ambisense S segment RNA of RVFV. In those studies, mutational analysis of the terminal nucleotides revealed that the first 13 nucleotides are required for polymerase recognition, but that one of the two terminal dinucleotides (UGUG) could be removed without deleterious effects on transcription.⁴²⁴ These data also suggested that realignment is not a prerequisite for transcription initiation. In contrast, a recent study using the BUNV minigenome system showed that the viral polymerase was able to repair both insertions and deletions in model template RNAs, although this did not appear to involve the prime-and-realign mechanism.⁵⁵⁹

Schematics of transcription and replication based on information above are presented in Figures 42.5 and 42.6.

Encapsidation Signals

Signals for the encapsidation of the vRNAs and cRNAs of orthobunyaviruses, phleboviruses, nairoviruses, and hantaviruses were found entirely within the noncoding 3' and 5' regions of minireplicon reporters.^{52,154,155,157,321,345,348,382} Mutational

FIGURE 42.6. Transcription and replication scheme of ambisense-sense bunyavirus genome segments. The genome RNA encodes proteins in both negative- and positive-sense orientations, separated by an intergenic region that for some viruses has the potential to form a hairpin structure. The proteins are translated from specific sub-genomic messenger RNAs (mRNAs), with the mRNA encoding protein 2 transcribed from the antigenome RNA after the onset of genome replication.

analysis of these terminal regions for BUNV revealed a conserved sequence within nucleotides 20–33 of the 5′ end of vRNA that was critical for packaging.²⁷⁰ Variable packaging efficiencies were noted for the L, M, and S segment–derived minireplicons, and packaging appeared to be independent for each.

Host Factors

Beyond the need for host-derived primers for initiating mRNA synthesis, little is known about the role that host factors might play in viral replication. One putative host transcription factor is an ~40-kD protein isolated from the main insect vector of TSWV, and it was shown to bind to the viral RdRp at its C-terminus and to the viral RNA at its N-terminus.¹¹⁹ Both this protein and reticulocyte lysates were needed for RNA synthesis *in vitro*, indicating that other cellular factors are also required. Expression of this protein in mammalian cells rendered them permissive to TSWV replication.¹¹⁹ As is the case for a number of other negative-strand RNA viruses, heat-shock protein 90 (Hsp90) appeared essential for La Crosse virus replication in that virus yields were diminished in cells treated with Hsp90 inhibitors like geldanamycin due to destabilization of the viral L protein.¹⁰⁵

Translation and Processing of Viral Proteins

Viral polypeptides are synthesized shortly after infection, with S and L mRNAs translated on free ribosomes and M mRNAs translated on membrane-bound ribosomes. Expression products vary among the genera, and even within a genus.

S Segment Products: N and NSs

The N protein is the most abundant viral product in virions and infected cells. N plays several important roles in viral replication. In addition to protecting the RNA from degradation, N also interacts with L and Gn and Gc, although the exact interactions have not been defined. A critical step in N interaction with RNA appears to be the ability of the proteins to oligomerize. Oligomerization characteristics of the N proteins are likely different among the genera, which is probably not surprising, given the size differences of the N proteins, which range from approximately 19kD for orthobunyaviruses to 54kD for hantaviruses and nairoviruses (Table 42.2).

Chemical cross-linking studies indicated that the ribonucleocapsids of the phlebovirus RVFV, either from authentic virions or reconstituted from bacterially expressed protein, contain dimers of N as the basic oligomer.^{297,440} The crystal structure of RVFV N has been determined to 1.93Å resolution, which revealed that it has a novel all-helical fold without a positively charged surface RNA binding cleft as seen for other negative-sense RNA virus nucleocapsid proteins.⁴⁴⁰ Extensive ribonuclease digestion of authentic or reconstituted RNAs released heterogeneous N-RNA multimers, consistent with the lack of observed helical symmetry. In contrast, hantaviral N proteins form stable trimers, which are postulated to assemble on the viral RNA, followed by further protein–protein interactions that encapsidate the entire RNA.²⁴⁹ The N–N interactions are likely to be electrostatic, with both amino- and carboxy-terminal residues participating.²⁵⁰ The N-terminal residues of hantaviral N proteins are predicted to form a coiled coil domain, providing a trigger for trimerization, and containing charged residues important for intermolecular interactions.^{9,10,13,562} For

TULV, carboxy-terminal amino acids 393 to 398 were shown to be crucial for trimerization, and amino acids 1 to 43 provided a secondary interaction region.²⁴⁹ These data are in agreement with those obtained with other hantaviruses (e.g., SNV and HTNV, for which carboxy-terminal and amino-terminal regions were shown to be involved in the homotypic interactions of N).^{9,589}

Orthobunyaviruses and tospoviruses, in contrast to hantaviruses, do not appear to assemble preformed trimers, but instead multimerize by adding one N protein at a time. This hypothesis comes from chemical cross-linking experiments, which showed that the N protein of the orthobunyavirus BUNV was able to form a range of multimers from dimers to high-molecular-weight structures, with a preponderance of tetramers.³⁰⁸ Deletion of N- or C-terminal portions of N prevented multimerization and also resulted in loss of functionality in a minireplicon system. The data were interpreted to indicate a head-to-head and tail-to-tail multimerization model of individual N proteins. Likewise, for the tospovirus TSWV, analysis of deletion mutants identified binding regions both at the amino- and carboxy-termini of N, and although the type of multimers formed was not examined closely, it appears to be a continuous addition process, like that proposed for the orthobunyaviruses.^{242,540}

In addition to protein–protein interaction, the amino- and carboxy-terminal regions of the tospovirus N were also implicated in RNA binding.⁴⁴⁷ In contrast, the RNA-binding site of hantaviral N was localized to a central, conserved region of the protein.⁴⁷⁴ For hantaviruses and bunyaviruses, RNA-binding studies with bacterially expressed, hexahistidine-tagged N proteins indicated that N preferentially interacts with the 5′ end of the vRNA.^{385,475} In another study, high-affinity binding of hantaviral N to panhandle RNA was demonstrated, and it was suggested that such binding is related specifically to the trimers, which were able to discriminate viral from nonviral RNA, whereas monomer or dimer subunits bound nonspecifically to RNA.³⁴⁸ These data suggest a requirement for multimerization of N for effective RNA binding and encapsidation, and implicate the panhandle structure as the trigger for encapsidation. Hantavirus N is also able to bind 5′ capped mRNAs (to generate a source of primers for transcription initiation; see above), and the cap and vRNA binding sites have been mapped to separate domains within the protein.³⁴⁹ Furthermore, binding to the mRNA cap induces a conformational change in N, and the structurally altered N loaded with the capped primer binds specifically to the conserved 3′ terminus of vRNA.

The S segments of viruses in the *Phlebovirus* and *Tospovirus* genera and some viruses in the *Orthobunyavirus* and *Hantavirus* genera produce NSs proteins as well as N proteins. Sizes of NSs range from 10 kD for orthobunyaviruses and hantaviruses to more than 50 kD for tospoviruses (Fig. 42.2). The NSs protein of the phlebovirus RVFV is phosphorylated and accumulates in the nuclei of infected cells, where it forms fibrillar structures (e-Fig. 42.4).⁵¹³ The major phosphorylation sites of the RVFV NSs were mapped to serine residues located near the carboxy-terminus of the protein.²⁶⁷ Expression studies revealed that fibrils could form in the absence of other viral proteins; however, if the carboxy-terminal region of NSs was removed, NSs were still transported to the nuclei, but did not coalesce into fibrils.⁵⁸⁴ Similar fibrillar structures of NSs were observed for some strains of TSWV, but the structures appeared only in the cytoplasm.

Comparing the deduced amino acid sequences of NSs for five different phleboviruses revealed homologies of only 17% to 30%.¹⁷⁸ However, comparison of the NSs gene sequences for a number of strains of a single phlebovirus RVFV showed that certain areas were highly conserved.⁴⁵⁹ These data suggest that there may be a strong evolutionary pressure to maintain distinct portions of the NSs for individual viruses, but that the remainder of the protein can diverge without affecting the function of NSs.

Earlier work suggested that the NSs of phleboviruses and tospoviruses were only synthesized after viral replication; that is, after the ambisense vRNA has been copied to cRNA and mRNA was transcribed from cRNA. Recent work with RVFV, however, indicates that at least for this phlebovirus, virions can encapsidate cRNA and that the incoming cRNA ribonucleocapsids can serve as templates for NSs mRNA.²²⁵ The outcome of this is that NSs are present early in infection and might have a role in early replication. The NSs of three orthobunyaviruses all inhibited BUNV RNA synthesis in a dose-dependent manner in a minireplicon system.⁵⁶⁷ The results were suggested to indicate a function for NSs in regulating the activity of the RdRp. In addition to a possible role for NSs in early replication processes, NSs proteins have other important roles in viral infection, such as interferon antagonism, host-range determination, and gene silencing. These effects will be described in the context of effects on host cells.

M Segment Products: Gn, Gc, and NSm

The viral envelope GPs Gn and Gc are translated from a single mRNA complementary to vRNA. The polyprotein precursor of Gn and Gc is not seen in infected cells, and has been observed only by *in vitro* translation of RNA transcripts in the absence of microsomal membranes.⁵⁴² For most viruses, both Gn and Gc are preceded by signal sequences; therefore, cleavage of the polyprotein precursor is likely mediated by host signalase.¹⁵⁰ A pentapeptide motif, WAASA, which is highly conserved among hantaviruses, was shown to be the polyprotein cleavage site for HTNV, by mutational analysis of the signal sequence preceding Gc.³¹⁸

M-segment gene products have a cysteine content of approximately 4% to 7%. Positions of these residues are highly conserved in the M-segment products of related viruses, suggesting that extensive disulfide-bridge formation may occur and that the positions may be crucial for determining correct polypeptide folding. The secondary structure of the proteins is also involved in immunogenicity, as indicated by the finding that neutralizing or protective epitopes are often nonlinear.

All M-segment polyproteins display variable numbers of predicted transmembrane regions, and a hydrophobic sequence at the carboxy-terminus, indicative of a membrane anchor region. Therefore, the M-segment translation products of viruses in the family *Bunyaviridae* are typical class 1 membrane proteins, with the amino terminus exposed on the surface of the virion and the carboxy-terminus anchored in the membrane.

The Gn and Gc proteins of all viruses in the family possess asparagine-linked oligosaccharides. Examination of the oligosaccharides attached to the Gn and Gc proteins of orthobunyaviruses revealed that Gc has mostly high-mannose glycans, whereas Gn contains both complex and a novel intermediate-type oligosaccharide.^{326,377,479} In contrast, the GPs of hantaviruses were found to be mostly of the high-mannose type.⁴⁶⁷ These

findings indicate that the proteins are incompletely processed through the Golgi. This is likely related to retention of Gn and Gc in the Golgi, where assembly occurs, and which will be discussed more fully.

Nairoviruses appear unique among viruses in the family in that they have both N-linked and a region of heavily O-linked carbohydrates (a mucin-like domain, as will be described).⁴⁶¹

The M-segment gene-product processing events differ among the genera. Hantaviruses produce only Gn and Gc,⁴⁷¹ whereas some viruses in the *Phlebovirus* and *Orthobunyavirus* genera produce NSm from the same M-segment mRNA as Gn and Gc. The NSm protein of orthobunyaviruses is encoded between the Gn and Gc proteins.¹⁴⁹ Its hydropathy profile suggests that it is a membrane-bound protein, and expression studies demonstrated that it localizes to the Golgi along with Gn and Gc.³⁰¹ Although a function for this protein has not been identified, it was suggested that it might be involved in facilitating virion assembly in the Golgi.³⁰¹

For the phlebovirus RVFV, a NSm of approximately 14 kD is cleaved from the amino-terminus of the polyprotein translation product (e-Fig. 42.5). Sequence studies revealed five in-frame translation initiation codons (AUG) upstream of the amino-terminus of Gn. Mutational analysis of those codons indicated the fourth and the fifth AUGs to translate Gn and Gc. Whilst NSm was found to originate from the second AUG and a 78-kD polypeptide, representing uncleaved NSm and Gn, was translated from the first AUG.¹⁹⁸ Pulse-chase experiments revealed no precursor-product relationship between the 78- and 14-kD proteins; therefore, it appears that use of the first and second AUGs, respectively, is what dictates generation of these proteins.⁷⁷ Both the 14-kD NSm and the 78-kD polypeptide are found in abundance in RVFV-infected cells,⁷⁸ suggesting that they might play a role in replication or morphogenesis.

An even larger NSm (~30 kD) is cleaved from the amino terminus of the M-segment polyprotein of the phlebovirus, PTV (e-Fig. 42.5). *In vitro* expression studies indicated that both envelope GPs could be produced in the absence of the NSm coding region,³³⁵ but other studies to evaluate the use of the 13 potential translation initiation codons present in the NSm coding information have not been reported. No homology between the NSm proteins of PTV and RVFV was apparent.²²¹

In contrast to the mosquito-borne phleboviruses PTV and RVFV, the tick-borne phlebovirus UUKV does not produce an NSm (e-Fig. 42.5). The first (and only) initiation codon preceding sequences of the envelope GPs is located 17 amino acids upstream of the amino terminus of Gn⁴⁴⁹; hence, the Gn protein of UUKV appears to be analogous to the 78-kD NSm-Gn fusion product produced by RVFV (although there is no obvious sequence homology of these predicted products). Until a function can be assigned to NSm, it is impossible to determine whether UUKV replicates in the absence of such a function or accomplishes whatever function is required without removal of a portion of the amino terminus of Gn.

M-segment polyprotein processing events for nairoviruses are more complicated and appear to differ from those of other viruses in the family (e-Fig. 42.6). Nucleotide sequences of DUGV, CCHFV, and NSDV revealed a coding strategy similar to other viruses in the family, that is, a single ORF.³³¹ Studies on CCHFV demonstrated the polyprotein is co-translationally

cleaved into 140-kD PreGn and 85-kD PreGc precursors and a 15-kD NSm protein.^{14,44,461,462,555} PreGn is processed to the mature 37-kD Gn by cleavage with a cellular secretory pathway protease, SKI-1, following a consensus motif, RRL_nL, early in the secretory pathway.⁴⁶¹ SKI-1 cleavage generates a subprecursor of the other two polypeptides that is cleaved by a furin-like protease late in the secretory pathway.⁴⁶¹ This cleavage site is completely conserved among several CCHFV strains, suggesting that it has importance for viral replication or pathogenicity.⁴⁶¹ The amino-terminal portion of this subprecursor is a highly variable (among CCHFV strains) polypeptide with mucin-like characteristics, including numerous serines, threonines, and prolines and predicted extensive O-linked glycosylation. The carboxy-terminal portion of the subprecursor is a 38-kD nonstructural polypeptide. After furin cleavage, secreted proteins GP38, GP85, GP160, and the mucin-like protein are produced; presumably these products reflect extensive O-linked glycosylation differences. Although the PreGc precursor also possesses a SKI-1-like cleavage motif, SKI-1 cleavage could not be demonstrated for this protein, so it is likely that a related enzyme is responsible for the processing to yield mature Gc.⁴⁶¹

Unlike all other viruses in the family, the NSm protein of tospoviruses is translated from an ambisense mRNA.²⁷⁴ It is also the only NSm protein in the family to have a definitively assigned function. By subcellular fractionation of infected plants, or in thin-section immunoelectron microscopy studies, the NSm of TSWV was found to be present in cell wall-containing fractions or associated with aggregates of nucleocapsids and with the plasmodesmata.²⁷⁵ Expression of the NSm protein in plant cells or insect cells revealed that the protein first appeared near the cell surface and later as tubular structures protruding from the cell surface. In infected leaf tissues, the tubules were observed only in the plasmodesmata.⁵¹⁰ These data are characteristic of proteins able to aggregate into plasmodesmata-penetrating tubules that allow cell-to-cell movement of the virus across the cell walls in infected plants. In several other studies, the TSWV NSm protein was shown to have additional characteristics of plant movement proteins, including sequence similarity, expression during the early stages of infection, and RNA-binding activity. Formal proof of this function was obtained from experiments in which NSm of TSWV was able to complement cell-to-cell movement of a movement-defective tobacco mosaic virus vector.⁵¹¹ This expression system was also used to show that NSm alone induced tubule formation in protoplasts and induced TSWV-like symptoms in *Nicotiana benthamiana*. Separate domains within NSm have been mapped for each of these functions.⁵¹² NSm was found to be expressed in its natural thrip insect vector, but did not aggregate into tubules, leading to the suggestion that NSm might only have a role in the plant portion of the tospovirus replication cycle.⁵¹¹

L Segment Product: L Polymerase Protein

The L proteins of bunyaviruses range in size from about 237 kD for phleboviruses, to 459 kD for nairoviruses (Fig. 42.2). There are no known processing or posttranslational modifications to the L proteins.⁵⁴⁶ Although structural analysis of an L protein from the family *Bunyaviridae* is not yet available, several features common to other polymerase proteins have been observed.²⁸²

The overall shape of the polymerase is compared to that of a right hand, with fingers, palm, and thumb domains. Four major conserved motifs in the palm region, designated as A–D are shared by many viral polymerases. Motifs A and C are involved in divalent cation use, whereas motifs A and B may be involved in sugar and nucleoside triphosphate selection. Motif C contains the catalytic core of the protein. For BUNV, site-directed mutagenesis demonstrated the importance of amino acids in motif C for polymerase activity.²³⁷ Alignment of the amino acid sequences of L proteins of several viruses in the family *Bunyaviridae* demonstrate the presence of A–D motifs in these proteins. In addition, two novel regions, found at the amino-terminus of the L protein of the phlebovirus RVFV, were shown to be conserved only in the polymerases of viruses in the *Bunyaviridae* and *Arenaviridae* families.³⁶¹

The function of the L protein as an RNA-dependent RNA polymerase was first confirmed by using L protein expressed from vaccinia virus recombinants to transcribe authentic orthobunyavirus ribonucleocapsid templates.²³⁶ Endonuclease activity was demonstrated *in vitro* with expressed BUNV L protein, providing evidence that the L protein is also responsible for generating the capped primers needed for transcription,²³⁶ and this was confirmed by expression of an N-terminal fragment of LACV L protein.⁴⁴²

Morphogenesis

Transport of Viral Proteins

In contrast to other negative-strand RNA viruses, bunyaviruses usually mature within cells by budding at smooth membranes of the Golgi (e-Fig. 42.7). The plant-infecting members of the family, the tospoviruses, also appear to assemble in the Golgi; however, it was suggested that instead of budding, there is a coalescence of Golgi membranes around the ribonucleocapsids.²⁵⁸ Budding at membranes other than those associated with the Golgi have been reported for some viruses; for example, the hantaviruses, SNV, and Black Creek Canal virus (BCCV), and the phlebovirus RVFV were found to bud from the plasma membrane as well as in the Golgi in some cells.^{17,437} The reason(s) for maturation of viruses in the family *Bunyaviridae* in the Golgi complex as opposed to the more usual mode of viral morphogenesis (budding at the plasma membrane) are not understood completely; however, important clues have been obtained by studying the viral proteins, transport to and retention in the Golgi.

Golgi Targeting and Retention

Expression of M gene segments of representative bunyaviruses demonstrated that Gn and Gc are targeted to the Golgi in the absence of other viral components. When expressed individually, Gn is able to exit the ER, but Gc remains in the ER for the orthobunyaviruses, phleboviruses, nairoviruses, and tospoviruses.^{45,262,294,334} For hantaviruses, neither protein exits the ER when expressed separately.^{454,482} For all studies to date, the signal for Golgi transport has been localized to Gn and complexing of Gn and Gc in the ER is necessary for efficient transport of Gc to the Golgi.

Although ER retention signals have not been identified on Gc for most viruses, the phleboviruses have a characteristic carboxy-terminal ER retention motif (KKXX, where K = lysine and X = any amino acid).¹⁷⁶ Evidently, this signal can be overcome when Gn and Gc oligomerize.

To map the Golgi targeting and retention signal(s) on Gn of orthobunyaviruses or phleboviruses, a series of deleted and/or chimeric genes were constructed and their expression products were examined for Golgi targeting and retention. For BUNV, the Golgi localization and retention signal was mapped to the transmembrane domain of Gn.⁴⁸⁵ The Golgi localization signal for the phleboviruses PTV and RVFV were identified within the transmembrane domain plus 10 (PTV) or 28 (RVFV) amino acids of the cytoplasmic tail.^{176,334} The Golgi localization signal of another phlebovirus, UUKV, was found to be within a 30 amino acid peptide of the cytoplasmic tail.¹⁸

Similar expression studies with M-segment constructs of HTNV indicated that the ability of Gn to transport Gc to the Golgi requires the presence of the complete signal sequence of Gc. This suggests that the Gc signal peptide remains attached to the Gn cytoplasmic tail. This signal alone, however, is apparently not sufficient for Golgi targeting because M segment constructs that maintained the Gc signal peptide but had other internal deletions in Gn or Gc failed to reach the Golgi. These results were interpreted to indicate that the correct conformation of the oligomerized Gn and Gc is also important for Golgi targeting.⁴⁷¹ Consistent with this is the observation that overexpression of SNV Gn resulted in the apparent accumulation of misfolded proteins in aggresomes.⁵⁰⁴ In addition, the cytoplasmic tail of Gn was found to be polyubiquitinated when expressed alone, suggesting that it would undergo proteasomal degradation if not complexed with Gc.¹⁷²

For the nairovirus, CCHFV, removal of the transmembrane domain and cytoplasmic tail of Gn did not prevent Golgi targeting, and this soluble truncated Gn was still able to dimerize with Gc and transport both proteins to the Golgi.⁴⁵ In another study, Golgi targeting was dependent both on a signal found in the hydrophobic region of the cytoplasmic tail, as well as in the ectodomain¹⁹⁶; therefore, unlike other bunyaviruses, nairoviruses appear to have at least part of their Golgi-targeting signal in the ectodomain, rather than only in the transmembrane or cytoplasmic tail regions of Gn.

Clearly, although there are definite signals targeting the viral glycoproteins to the Golgi, there is no consensus motif or even region of Gn conserved among viruses in the family.

Trafficking Through the Golgi

The Golgi complex consists of several subcompartments, including the cis-, medial-, and trans-Golgi.²⁶⁴ By using the fungal antibacterial reagent Brefeldin A, which inhibits transport of proteins out of the ER and causes a redistribution of the Golgi component to the ER, the GPs of the phlebovirus PTV were found to be localized in the cis and medial Golgi membranes.⁹³ Similar redistribution of Gn and Gc from the Golgi to the ER were observed following Brefeldin A treatment of cells infected with vaccinia virus recombinants expressing the M segment of BUNV.³⁶⁶ Immunohistochemical and electron microscopy studies of the phlebovirus UUKV demonstrated that budding may begin as early as the pre-Golgi intermediate compartment and that virus budding continues in the Golgi stack.^{232,458}

Examination of the type and amount of oligosaccharides attached to viral proteins influences trafficking and provides clues regarding the transit of the proteins through the Golgi compartments. For example, shortly after primary glycosylation of nascent proteins at the ER, oligosaccharides are susceptible

to cleavage by endoglycosidase H (endo-H), an enzyme that cleaves only high-mannose residues. Later, after removal of glucose residues at the rough ER, migration of the GPs to the smooth ER and Golgi, trimming of residues, and attachment of peripheral sugars, the oligosaccharides are no longer susceptible to endo-H cleavage. Therefore, acquired resistance to endo-H generally indicates that the proteins have been processed through specific Golgi compartments as described earlier (see "M segment products"). For the nairovirus CCHFV and the hantavirus HTNV the GPs remain endo-H sensitive, suggesting that they have not been processed through the medial Golgi.^{45,480} In contrast, the GPs of the orthobunyavirus, BUNV become endo-H-resistant, so they can be assumed to have moved through the trans-Golgi.³⁷⁷

To identify the roles of specific glycosylation sites on trafficking of HTNV GPs, a series of expression constructs were created in which each of the four glycosylation sites that are used on Gn and the single site used on Gc were mutated. Removal of the glycosylation site closest to the amino-terminus of Gn resulted in its inability to exit the ER and for a loss of reactivity with monoclonal antibodies to native Gn.⁴⁸⁰ Mutating the third glycosylation site in Gn was also poorly tolerated, and resulted in inefficient Golgi targeting and loss of monoclonal antibody reactivity. In contrast, mutating the single site on Gc or two of the other three sites of Gn were well tolerated. A similar study with BUNV indicated that the single Gn glycosylation site is absolutely required for correct protein folding, trafficking, and infectivity.⁴⁷⁹ These data are consistent with results from another study, which will be described below, indicating that the processing of sugars plays a key role in maturation of BUNV.³⁷⁷

The time required to convert between endo-H susceptibility and resistance correlates with the time needed for protein transport from the ER to the Golgi. For the phlebovirus PTV, heterodimerization occurred between newly synthesized Gn and Gc within 3 minutes after protein synthesis, and the dimers were found to be linked by disulfide bonds. The dimeric Gn-Gc proteins were observed both during transport and after accumulation in the Golgi complex.⁹³ For another phlebovirus, UUKV, it was found that the transport of Gn and Gc from their site of synthesis on the rough ER through the Golgi occurred at an estimated two to three times slower rate than that of most viral membrane GPs destined to be transported to the plasma membrane.¹⁶⁶ That is, endo-H resistance was achieved at 45 and 90 to 150 minutes for Gn and Gc of UUKV,²⁸¹ compared to 15 to 20 minutes for the hemagglutinin protein of influenza virus or the G protein of vesicular stomatitis virus. The finding that UUKV Gn and Gc have different transport kinetics (i.e., Gn is incorporated into virions 20 minutes faster than Gc) suggests that the dimers may arise from different precursor proteins, possibly because faster-folding Gn cannot dimerize with slower-folding Gc until Gc has reached its correct conformation.⁵⁸⁰ In this same study, the Gn and Gc proteins of UUKV were found to exit the ER quickly, but did not enter the Golgi for 15 to 20 minutes. These findings suggest that the Gn and Gc proteins may dimerize in an intermediate compartment between the ER and Golgi.⁵⁸⁰

The NSm proteins are not known to play a role in transport or Golgi retention. For representative phleboviruses and orthobunyaviruses, expression of Gn and Gc in the absence of NSm had no effect on their transport to the Golgi; however,

when the entire M segments were expressed, NSm co-localized to the Golgi with Gn and Gc, suggesting an interaction of these proteins before their exit from the ER.

Assembly

For assembly to occur, N as well as Gn and Gc must move to the same intracellular location. For the hantavirus, SEOV, N could first be observed approximately 2 hours after infection and accumulated as scattered granules in the cytoplasm. Although N was not observed in the Golgi, it could be observed to surround the Golgi by 24 hours after infection.²⁴⁷ The N proteins of theairovirus CCHFV and the hantavirus BCCV were both observed in the perinuclear region of infected cells, and both were found to bind to actin.^{21,436} Disrupting the cellular actin network by treatment with cytochalasin D, reduced the assembly of infectious CCHFV, suggesting a role for actin in transporting N to the site of virion assembly. For BCCV, the N protein was found to be peripherally associated with Golgi membranes, suggesting that the ribonucleocapsids are recruited to the Golgi for assembly.⁵⁰⁴ In contrast, the CCHFV N protein was not found in association with Golgi membranes; therefore, it is unclear where the actual assembly site is forairoviruses, and it was suggested that some sort of novel structure close to the nucleus might be involved in bunyavirus assembly.²¹

This was confirmed by detailed electron microscopic analysis of BUNV-infected cells, which identified viral replication

occurring in a “viral factory” that is built around the Golgi complex (Fig. 42.7) and comprises repetitive units of Golgi stacks, mitochondria, components of the rough ER, and virus-derived tubular structures with a globular head.⁴⁵⁸ The viral polymerase and N protein were found mainly in the globular head, and viral RNPs were released from disrupted, purified tubes.¹⁵⁹ Viral tubes contain cellular proteins such as actin and myosin I, and both tube assembly and viral morphogenesis were sensitive to drugs that affect actin. Advanced imaging and three-dimensional (3D) reconstruction of infected cells showed that the tubes link cellular organelles, for example, mitochondria, to the Golgi and interact with intracellular viral forms, thereby providing a route for cellular factors required for genome replication. Based on these observations a model has been proposed (e-Fig.42.8) whereby viral RNPs are transported from sites of replication in the globular domain to the cytoplasm where they condense on Golgi membranes modified by the insertion of Gn and Gc, and promote budding of immature particles into Golgi-derived vesicles.

Unlike most other negative-strand RNA viruses, members of the *Bunyaviridae* do not have an M protein to link the integral viral envelope proteins and their nucleocapsids and to act as the nucleating step for assembly. The absence of M protein suggests a direct interaction between the ribonucleocapsids, which accumulate on the cytoplasmic side of vesicular membranes, and viral envelope proteins, which are displayed on the

FIGURE 42.7. Visualization of viral factory in Bunyamwera virus (BUNV)-infected BHK cells by electron microscopy.

A: Viral factory (dashed white circle) shows groups of organelles near the nucleus (N). **B:** Higher magnification shows longitudinal (arrow) and transverse (arrowhead) sections of tubular structures in Golgi stacks (G). Virus particles (V) are also seen. **C:** Tubular assembly with a bigger globular domain (arrow). N, nucleus; G, Golgi stack; V, virus particle; scale bar represents 1 μm in (A). (Modified from Fontana J, Lopez-Montero N, Elliott RM, et al. The unique architecture of Bunyamwera virus factories around the Golgi complex. *Cell Microbiol* 2008;10:2012–2028.)

luminal side. Electron microscopy of cells infected with the phleboviruses PTV or Karimabad virus, revealed that ribonucleocapsids and spike structures (i.e., viral envelope GPs) were present only in regions of Golgi membranes where budding appeared to be occurring, and not on adjacent areas of the same membrane, suggesting a transmembranal interaction of N with Gn or Gc.⁴⁹⁷ Direct evidence for the requirement of the cytoplasmic tails of both glycoproteins has been obtained using virus-like particle production assays.⁴⁸⁴

The signal directing the ribonucleocapsids to the budding compartment has not been identified for most viruses in the family. For hantaviruses, however, N was shown to interact with the cellular proteins, SUMO-1 (small ubiquitin-like modifier-1) and Ubc9 (SUMO-1 conjugating enzyme 9) in yeast two-hybrid systems.^{251,301,327} For HTNV, the interaction occurred at a four amino acid motif, MAKE, located at amino acid positions 188 and 189 of N, and mutation of this motif prevented transport of N to the perinuclear region, suggesting a role for this interaction in directing N to the site of assembly.

Excess ribonucleocapsids of hantaviruses, tospoviruses, and nairoviruses were found to accumulate in large cytoplasmic inclusions, suggesting that only ribonucleocapsids that interact with the envelope proteins are transported to the Golgi. Although not yet defined, it is likely that the transmembrane domains of Gn or Gc that are exposed on the cytoplasmic face of the membrane are involved in this interaction. Candidate transmembrane regions have been predicted from hydrophobic characteristics of derived amino acid sequences representing the envelope proteins of all bunyaviruses examined to date. Direct examination of a phlebovirus by enzymatic digestion of exposed proteins embedded in intracellular membranes, demonstrated that approximately 12% of Gn or Gc was exposed on the cytoplasmic face of membranes in infected cells and was accessible to digestion. A large protease-resistant fragment was identified, which was presumably sequestered in the membrane in a manner that rendered it safe from enzymatic digestion.⁴⁹⁷ These enzyme-resistant fragments may therefore represent transmembrane regions of proteins, which could provide the interaction between ribonucleocapsids and the cellular membranes required for envelopment. The predicted cytoplasmic tails on Gn have also been suggested to be logical candidates for interacting with the ribonucleocapsids.⁴⁴⁴

Tospovirus assembly and release in plants may differ from those processes of other viruses in the family. A model was proposed in which Golgi membranes with integral viral envelope proteins wrap around ribonucleocapsids. These particles may then fuse with each other or with ER membranes to release single enveloped particles into the cisternae.²⁵⁸ Mature virions accumulated within the ER cisternae likely remain there until ingested by thrips.

For BUNV, the complete suite of L, M, and S packaging signals was not required for generation of infectious virus as a virus lacking the L segment UTRs (the L ORF was flanked by the complete UTRs from the M segment) was created by reverse genetics.³²¹ In contrast, a recent study on RVFV packaging suggested M-segment UTRs, particularly a region in the 5'UTR, was critical for co-packaging of the L and S segments.⁵²⁶

Transport and Release

After budding into the Golgi cisternae, virions apparently are transported to the cell surface within vesicles analogous to those

FIGURE 42.8. Bunyavirus transport by exocytosis. BSR-T7/5 cells were infected for 8 h with a recombinant Bunyamwera virus (BUNV) expressing a Gc-GFP (green fluorescent protein) fusion protein and co-stained with an anti-tubulin antibody (*in red*). Progeny virions in vesicles en route to the plasma membrane are visible as *green dots*. (From Shi X, van Mierlo JT, French A, et al. Visualizing the replication cycle of Bunyamwera orthobunyavirus expressing fluorescent protein-tagged Gc glycoprotein. *J Virol* 2010;84:8460–8469.)

in the secretory pathway. The release of virus from infected cells presumably occurs when the virus-containing vesicles fuse with the cellular plasma membrane (i.e., by normal exocytosis). Numerous viruses in the family have been observed late in infection within vesicles or in the process of exocytosis by electron microscopy, and more recently by light microscopy of BUNV expressing a Gc-GFP fusion protein (Fig. 42.8). In polarized cells, the phleboviruses PTV and RVFV show differing release characteristics, in that no marked polarized release could be detected for RVFV, whereas PTV was released primarily from the basolateral surfaces.^{94,177} In contrast to these phleboviruses, the hantavirus BCCV was released from the apical surface.⁴³⁷ Such polarized release of viruses might be important for disseminating virus during natural infection to produce a systemic disease. Release of tospoviruses from insect cells probably occurs via secretory exocytosis similar to that of animal-infecting members of the family.⁵⁷⁹

EFFECTS OF VIRAL REPLICATION ON HOST CELLS

Cytopathic Effects

The cytopathic effects observed in cultured cells infected with members of the family *Bunyaviridae* vary widely, depending both on the virus and the type of host cell studied. Viruses in all genera except for the *Hantavirus* genus are capable of alternately replicating in vertebrates (or plants for tospoviruses) and arthropods, and generally they are cytolytic for their vertebrate/plant hosts but cause little or no cytopathogenicity in their invertebrate hosts. Some viruses display a narrow host range, especially for arthropod vectors. Although the reason for this has not been defined completely, studies on variant and revertant LACV orthobunyaviruses have suggested that

the specificity was related to Gc, probably at the level of viral attachment to susceptible cells.⁵¹⁵ In natural infections of mammals, viruses are often targeted to a particular organ or cell type. For example, orthobunyaviruses such as LACV appear to be neurotropic³⁹⁶; the phlebovirus RVFV is primarily hepatotropic⁴⁰⁷; and the hantavirus HTNV persists in rodent lungs.³⁰⁴ It will be interesting to determine whether this targeting is due solely to host-cell receptors or to other factors such as differences in effects on host-cell metabolism in targeted cell types versus the unnatural situation in cultured vertebrate cell lines.

Host-Cell Metabolism

In vertebrate cells, orthobunyaviruses and some phleboviruses were found to cause a reduction in host-cell protein synthesis, which became more prominent as the infection progressed. For example, by 5 hours after infection, cells infected with BUNV at high multiplicity showed reduced levels of host protein synthesis, and by 7 hours there was almost no synthesis.⁴⁰² RVFV-infected cells displayed reduced host protein synthesis, which gradually became more pronounced from 4 to 20 hours after infection.³⁹⁴ In contrast, a reduction in host protein synthesis did not occur, even late in infection, with another phlebovirus, UUKV, or with theairovirus DUGV,^{410,542} both of which are transmitted by ticks rather than mosquitoes. Hantaviruses not only cause no detectable reduction in host macromolecular synthesis,⁴⁶⁶ but routinely establish persistent, noncytolytic infections in susceptible mammalian host cells, a finding consistent with their nonpathogenic persistence in their natural rodent hosts.³⁰⁴

The arthropod-borne members of the family, like most other arboviruses, cause little detectable cytopathology in mosquito cell cultures, and viral persistence is readily established. Unlike cultured vertebrate cells, mosquito cells infected with the orthobunyavirus, Marituba virus, displayed no reduction in host macromolecular synthesis; therefore, viral infection apparently does not drastically interfere with normal cellular processes.⁸¹ One suggested reason for this is that, in arthropod cells, excess viral proteins do not accumulate in the cells but rather are more efficiently processed into mature virions.³⁶⁹ Another possibility is that viral transcriptase may be less active in arthropod cells than in mammalian cells and that the endonuclease activity of the polymerase (which is used to acquire transcriptional primers) is detrimental to host-cell messages. A reduced level of activity of the viral transcriptase would, therefore, produce less damage to host-cell messages and consequently to protein synthesis.⁴⁵¹

Persistence, both in insect and mammalian cells, can be mediated by defective interfering (DI) viruses. Conventional DI particles, which displayed deletions only in L, were described for orthobunyaviruses and tospoviruses. The L deletions identified both in the TSWV and BUNV DI particles were in-frame, thus allowing translation of truncated L polypeptides.^{116,397} Persistent infections of viruses in the family have also been described that do not involve typical DI particles, but instead are caused by infection with temperature-sensitive and plaque morphology mutants.

Host-Cell Responses and Viral Suppression Interferon-Stimulated Genes and Gene Products

A first line of host defense against viruses is the innate immunity mechanism mediated by the type I interferon (IFN) pathway. Type I IFN (also called IFN α/β) is produced in,

and secreted from, infected cells, and in neighboring cells activates the expression of hundreds of IFN-stimulated genes (ISGs) whose gene products directly or indirectly inhibit virus replication. IFN induction is mediated by the recognition of pathogen-associated molecular patterns (PAMPs) by cellular receptors.⁴¹² Two RNA helicases, RIG-I and MDA5, are intracellular receptors that are activated by RNA, though the double-stranded RNA (dsRNA)-binding protein kinase PKR may also assist.^{413,435,443,473} RIG-I binds short dsRNAs and also the 5' triphosphate groups on uncapped viral single-stranded RNA (ssRNA), whereas MDA5 recognizes long dsRNA. Negative-sense RNA viruses do not produce much dsRNA,⁵⁶⁸ although they are strong activators of RIG-I, probably because of the 5' triphosphate groups on their genomes. Activation of RIG-I by binding of RNA initiates a signaling cascade that leads to phosphorylation of the transcription factor IFN regulator factor 3 (IRF-3)²⁰⁵; phosphorylated IRF-3 dimerizes, enters the nucleus, and initiates IFN- β mRNA synthesis. Virus replication also activates other transcription factors such as IRF-7, NF- κ B, and AP-1, which enhance IFN gene expression. IFN-induced proteins have a myriad of functions, some of which have been characterized with respect to their specific antiviral activity. The three major antiviral defence mechanisms are the Mx protein, PKR, and the 2'-5' oligoadenylate synthase (2'-5'-OAS)/RNaseL system.

The Mx proteins are interferon-induced cytoplasmic proteins, which belong to a family of large GTPases that function in intracellular trafficking. After viral infection, Mx proteins are rapidly induced and accumulate in the cytoplasm. Human MxA has been shown to inhibit the replication of representative members of the *Orthobunyavirus*, *Hantavirus*, *Nairovirus*, and *Phlebovirus* genera.^{61,163,245,254} Both inhibition of primary transcription and genome replication have been observed.^{163,190,444} The MxA protein was shown to bind to the N proteins of LACV, BUNV, RVFV, ANDV, and CCHFV^{19,254,265,444} and in LACV infected cells to redistribute it into membrane-associated perinuclear cytoplasmic complexes, thus removing the protein from use in viral replication^{265,444}). For the orthobunyavirus LACV, MxA inhibits replication in mammalian cell cultures, in mosquito cells expressing the human MxA gene, and in MxA-transgenic mice that lack a functional IFN system.^{163,202,350}

Inhibition of the replication of several hantaviruses by MxA protein has been described. ANDV infection of human vein endothelial cells (HUVECs) was found to upregulate transcription of MxA RNA and expression of MxA protein. Virus replication was required for the induction of MxA, and the virus was found to replicate best in cells with low or no expressed MxA. Comparison of induction of MxA protein for pathogenic and nonpathogenic hantaviruses in HUVECs demonstrated that the nonpathogenic hantaviruses (PHV or TULV) induced an early and vigorous onset of MxA expression, whereas the pathogenic hantaviruses (ANDV or HTNV) induced MxA relatively late (48 hours) after infection.^{174,276} In contrast, Vero E6 cells, which lack IFN genes, supported the growth of both viruses. These results suggest that pathogenic, but not nonpathogenic hantaviruses, can delay the IFN- β induced antiviral MxA response and allow efficient viral replication early in infection.²⁷⁶

To determine whether MxA would be active against tospoviruses in plants, transgenic tobacco plants expressing MxA were created and then challenged with TSWV. No increased resistance to viral replication was observed in the transgenic

plants, indicating that expression of human MxA alone is not sufficient to impart virus resistance to plants.¹⁶⁴

In MxA-deficient systems bunyavirus replication can still be impaired, implying that other ISGs have anti-bunyaviral activity.^{20,56,191,381} PKR was shown to contribute to host resistance to BUNV, whereas 2'-5' OAS and RNaseL had no effect,⁵¹² and RVFV lacking its NSs protein is sensitive to PKR *in vitro* and *in vivo*.^{191,224} Other IFN-stimulated genes have been identified in hantavirus-infected cells. These studies were conducted mostly with the idea of understanding pathogenic mechanisms involved in disease and are discussed in more detail later. In one study, gene microarray analysis and reverse transcription-PCR revealed that a variety of ISGs, but not IFN genes, were turned on in response to infection or to treatment with ultraviolet-inactivated SNV.⁴²⁶ Because there was no IFN gene upregulation, it was suggested that IFN-independent pathways mediated the induction of the ISG, perhaps by binding of the viral particles to the $\beta 3$ integrin receptor that has been shown to be used by SNV and other pathogenic hantaviruses for entry via receptor-mediated endocytosis. Consistent with this, and with the aforementioned MxA study, differences in ISGs were observed at early times after infection of human endothelial cells with pathogenic or nonpathogenic hantaviruses, with the nonpathogenic hantavirus inducing much higher levels of ISGs as compared to pathogenic hantaviruses.¹⁷⁴

Interferon Antagonism

Because the IFN response induces an antiviral state in cells, most or all viruses encode one or more IFN antagonistic proteins, which allows them to overcome the effects of IFN early in infection. Evasion of the IFN response by viruses can occur by preventing IFN release or by inhibiting IFN-signaling and/or the activity of ISGs.

IFN antagonism has been demonstrated for the NSs proteins of the phlebovirus RVFV, the orthobunyaviruses BUNV and LACV, and the hantaviruses PUUV and TULV.²²⁷ For the phleboviruses and orthobunyaviruses, NSs were identified as IFN antagonists by comparing wild-type and mutant viruses that do not express NSs. A RVFV mutant, called Clone 13, was naturally occurring, whereas the BUNV and LACV mutants were created by reverse genetics.^{51,63,362} The wild-type viruses induced little IFN and were virulent in mice, whereas the NSs-defective viruses were potent inducers of IFN and attenuated in mice. In genetically altered mice that are nonresponsive to type 1 IFN, the mutant viruses were just as virulent as the wild-type parents, indicating that type 1 IFN is the target of NSs.^{53,63,265,566}

Although the orthobunyavirus and phlebovirus NSs have no sequence similarity and are expressed by different coding strategies, they both appear to antagonize host IFN at the level of cellular transcription. For BUNV and LACV, NSs was shown to inhibit phosphorylation of the C-terminal domain of the RNA polymerase II complex, leading to a downregulation of host mRNA synthesis.^{266,533,552} This effect was seen only in mammalian cells, not in insect cells, suggesting that IFN antagonism by NSs might be involved in the lytic infections observed in mammalian cells as opposed to viral persistence in insects.²⁶⁹ BUNV NSs was shown to interact with the protein MED8, a component of the Mediator complex that is essential for mRNA synthesis.³⁰⁷ LACV NSs selectively targets the RPB1 subunit of the elongating form of RNA polymerase II for proteasome-mediated degradation, an event similar to that

seen during the cellular DNA damage response.⁵⁵² RVFV NSs inhibits transcription of IFN mRNA in two ways, firstly by interacting with, and degrading, the p44 subunit of the TFIIF transcription factor,²⁹⁶ and secondly by recruiting the SAP30 repressor factor to the IFN- β promoter.²⁹⁸ The NSs proteins of the phleboviruses PTV and SFSV also block IFN induction^{191,404} whereas that of TOSV only blocked induction when expressed in a heterologous context.¹⁸⁴ In addition to interfering with the IFN response, BUNV NSs was also reported to delay apoptosis, probably by inhibiting some downstream effect of IRF-3 activation. This effect, however, was independent of the IFN response, in that the NSs-deleted BUNV also induced rapid apoptosis in a cell line that was not responsive to IFN. In a cell line that produces low levels of IRF-3, induction of apoptotic cell death by the wild-type and NSs deletion mutant was similar, suggesting that IRF-3 is involved in the BUNV-induced apoptotic pathways and that NSs somehow counteracts this effect.²⁶⁶ Orthobunyaviruses in the Anopheles A, Anopheles B, and Tete serogroups do not encode an NSs protein, and most behaved like a recombinant BUNV with the NSs gene deleted in failing to prevent induction of IFN- β mRNA.³⁵¹ However, Tacaiuma virus in the Anopheles A serogroup inhibited IFN induction similar to wild-type BUNV, suggesting that TCMV has evolved an alternative mechanism, not involving a typical NSs protein, to antagonize the host innate immune response.

Some hantaviruses have an additional ORF in the S segment,⁴²¹ and evidence for the expression of an NSs protein has been obtained for PUUV and TULV.²²⁷ The NSs protein was shown to be weakly antagonistic to IFN when overexpressed in cell culture, and the presence of a full-length NSs gave a growth advantage to TULV strains in IFN-competent cells.²²⁸ Both hantaviruses and nairoviruses have 5' monophosphorylated nucleotides on their genomes, thereby avoiding recognition by RIG-I and hence inducing IFN,¹⁸⁹ although the viruses also encode other countermeasures to innate immunity. The OTU domain in the nairovirus L protein deconjugates ubiquitin and ISG15 from cellular targets, thus antagonizing the antiviral effects of ISG15 and inhibiting NF- κ B dependent signaling.^{77,165,230} Certain hantaviruses have also been shown to interfere with TNF- α induced activation of NF- κ B signaling through an interaction between the viral N protein and karyopherin molecules that normally transport the NF- κ B subunits from the cytoplasm to the nucleus, thus preventing their use to activate ISG.⁵²³

As described above, it has been reported that pathogenic hantaviruses do not efficiently activate the IFN response as compared to nonpathogenic hantaviruses, suggesting the presence of an IFN antagonistic gene in pathogenic hantaviruses.¹⁷⁴ The cytoplasmic tail of the Gn glycoprotein (Gn-T) from pathogenic hantaviruses has been shown to downregulate IFN induction by interacting with TNF receptor-associated factor 3 (TRAF3), an adaptor protein for IRF-3 and NF- κ B signaling, whereas Gn-T from PHV fail to inhibit IFN induction.^{11,12} However, a recent paper demonstrates that the Gn-T of nonpathogenic TULV can also downregulate IFN induction, but does so in a manner not involving interaction with TRAF3.³³⁶ These data suggest that the pathogenic potential of hantaviruses does not depend on their ability to downregulate IFN alone. The situation is further complicated by the demonstration that for ANDV, IFN induction is inhibited by co-expression of the glycoprotein

precursor (GPC) and N protein, whereas downstream IFN signaling may be inhibited by either protein.³⁰⁹ In addition, hantavirus infection of VeroE6 cells was reported to result in induction and secretion of type III IFN (IFN- γ).^{425,509} Furthermore, the induction of ISGs in epithelial cell lines (e.g., A549 cells) infected with Vero cell grown virus was found to be due to the presence of IFN- γ rather than to virus infection.⁴²⁵

Cytokines/Chemokines/ITAMs

The host cells' responses to hantaviral infection have been studied in an attempt to understand the mechanism of disease. Hantaviruses cause two serious human disease syndromes: HFRS and HPS. Both HFRS and HPS are believed to result from host immune responses to viral infection, rather than damage caused by the viruses themselves.²⁵⁵ In both syndromes, vascular endothelial cells show increased permeability, which is believed to contribute greatly to the diseases. Several studies have measured the types of cytokines and chemokines released in response to disease, and these are discussed in the context of viral pathogenesis below. Of note is the presence of immunoreceptor tyrosine-based activation motifs (ITAMs) within the cytoplasmic tails of the Gn protein of hantaviruses. ITAMs are cell-signaling elements involved in regulating endothelial cell function. The presence of these elements in hantaviruses has also been suggested to relate to the dysregulation of endothelial cells during hantaviral infection.^{172,173}

Apoptosis

Apoptosis, or programmed cell death has been described for hantaviruses, orthobunyaviruses, and phleboviruses. Apoptosis usually results from activation of a proteolytic system involving caspases, a group of cysteine proteases that cleave cellular substrate proteins.

Apoptosis caused by a virus in the family *Bunyaviridae* was first noted in cultured cells and brains of newborn mice infected with the orthobunyavirus LACV.⁴⁰¹ The NSs proteins of LACV were found to have an amino acid sequence similar to that of a *Drosophila* protein, Reaper, which is involved in regulating caspase activity and can induce apoptosis.¹⁰⁴ Reaper is one of several proteins that are able to bind to a group of proteins, known as inhibitors of apoptosis, which function to control caspase activity.⁴⁸⁷ Like Reaper, BUNV NSs proteins were shown to both inhibit cellular protein translation and activate caspase in cell-free extracts. To demonstrate *in vivo* apoptosis, a Sindbis replicon expressing NSs was injected into the brains of young mice. The mice developed neuronal apoptosis and died 6 days after infection. A similar mechanism of action for inducing apoptosis by Reaper and orthobunyavirus NSs was proposed because both were shown to bind to and counteract the effects of a protein known as Scythe, which is an apoptosis regulator.¹⁰⁴ Mosquito cells persistently infected by LACV do not undergo apoptosis.⁵¹ Oropouche orthobunyavirus (OROV) induces apoptosis in HeLa cells that is dependent on virus uncoating and replication, and treatment of cells with a pan-caspase inhibitor did not affect virus production although apoptosis was prevented.³ The results indicated that the intrinsic apoptosis pathway was triggered by virus replication but apoptosis was not necessary for efficient virus production.

Apoptosis was also observed in the brains of adult Balb/c mice infected with a neurotropic strain of the phlebovirus

TOSV, but the mechanism of apoptotic triggering was not investigated.¹¹⁰

For several hantaviruses, apoptosis was observed in infected cultured monkey kidney (Vero E6) cells,^{246,313} in cultured human embryonic kidney cells (HEK-293),³³⁰ and in lymphocytes of HFRS patients.⁴ Unlike most infections with hantaviruses, which are generally noncytolytic and persistent, cytopathic effects were observed in the HEK-293 cells infected with hantaviruses, and apoptosis was observed almost entirely in cells adjacent to those actively infected with the hantavirus.³³⁰ In another report, apoptosis was not seen in confluent Vero E6 cells infected with various hantaviruses, and only a few apoptotic cells could be seen when subconfluent cells were infected.¹⁹⁸ Likewise, infection of primary immature dendritic cells or HUVECs with HTNV did not induce cell lysis or apoptosis.⁴²⁹ These differing results remain to be resolved, but it is likely that they can be attributed to differences in the cells or the condition and passage histories of the cells.

The factors triggering apoptosis for hantaviruses are not generally known. In TULV-infected Vero E6 cells, caspase 8 activation was observed and apoptosis could be inhibited with a caspase inhibitor.³¹³ Caspase 8 is one of several caspases that can be induced by the binding of a specific ligand to "death receptors," such as tumor necrosis factor 1 (TNF1) and Fas (also called CD95), which are found on certain cells.²⁹ Consistent with this, TNF1 was upregulated at times when apoptosis was apparent in the TULV-infected cells and a Fas-mediated apoptosis enhancer, Daxx, was found to bind to PUUV N proteins.³¹⁵ However, in another study, no significant increase in the mRNAs of the TNF superfamily was observed in hantavirus-infected HEK-293 cells.³³⁰

Stress on the host cell ER is another cellular condition that can trigger apoptosis. TULV infection of Vero E6 cells was noted to activate markers of ER stress, including induction of the chaperone protein, Grp78/bip, which was suggested to be induced by the accumulation of misfolded proteins in the ER.³¹⁴ Another cellular stress-response protein, heat shock protein 70, was found to be abundant in postmortem tissues of hantavirus-infected patients and to be upregulated in VeroE6 cells infected with HTNV.⁵⁸⁹ In this study, it was not clear what role the stress protein played in host-cell response to infection. Additional work is needed to identify the many possible factors that can contribute to cellular stress and apoptosis in bunyavirus-infected cells.

RNA Silencing

RNA silencing, or RNA interference (RNAi) was first described for plants as a mechanism to defend against viral infection, but is now known to occur in most eukaryotes. The gene silencing is mediated by short interfering RNAs (siRNAs), which arise from cleavage of dsRNAs, including the replication intermediates of RNA viruses by a host enzyme known as Dicer. The 21 to 25 nucleotide siRNAs become part of a protein complex known as the RNA-induced silencing complex, which recognizes and degrades sequence-specific mRNAs. Some viruses have been shown to produce suppressors to counteract the gene silencing mechanism. In the family *Bunyaviridae*, the NSs protein of the tospovirus TSWV was found to act as a suppressor of gene silencing.^{68,521} In addition to the plant-infecting bunyaviruses, siRNA suppression has been observed with the orthobunyavirus LACV, both in mammalian and insect cells,

and with the nairovirus Hazara virus (HAZV) in tick cells. As for the tospoviruses, the LACV-suppressing activity was localized to NSs, despite the completely different coding strategy used for this protein (i.e., ambisense vs. ORFs).⁵⁰² For HAZV, which does not produce an NSs protein, the activity was observed with the S-segment gene in either the sense or antisense orientation.¹⁶⁷

Although not yet demonstrated, it was suggested that the similarities of the ambisense-encoded NSs proteins of tospoviruses and phleboviruses would suggest similar functions in viral replication. It will be interesting to see whether the NSs of phleboviruses will have both interferon antagonistic activity (as described earlier) as well as RNAi activity. Such dual-pathogenic activity is known to occur for other viral proteins, for example, the NS1 protein of influenza virus.¹⁹⁷

PATHOGENESIS AND PATHOLOGY

Orthobunyavirus Genus

Human infections with California encephalitis, LACV, or Jamestown Canyon (JCV) viruses are initiated by the bite of a virus-infected mosquito. The course of the infection has been extensively modeled in mice.³⁹⁶ Similar to the human infection, the outcome of the infection in mice is dependent on the age of the animal and strain of virus used, with subcutaneous challenge of newborn mice most closely mimicking the natural human infection. The virus initially spreads from the site of inoculation into striated muscle, which is the major site of replication. It spreads to the plasma, presumably through the lymphatic channels, and the resulting high viremia allows the virus to cross the blood–brain barrier.²³¹ Mice inoculated intraperitoneally with LACV showed high levels of replication in nasal turbinates, suggesting the virus could enter the central nervous system (CNS) by olfactory neurons.³⁸ Once in the CNS, the virus replicates in neurons and glial cells, causing considerable neuronal necrosis. Death occurs 3 or 4 days postinfection. In contrast, although rhesus monkeys were highly susceptible to LACV infection, the animals remained asymptomatic and developed neutralizing antibodies.³⁸ High viremia is essential for neuroinvasion. A monoclonal antibody escape mutant of LACV (V22) showed decreased replication in striated muscle, and hence did not generate sufficient viremia to permit neuroinvasion, but V22 was as neurovirulent as wild-type LACV when inoculated intracranially.¹⁸² A similar distinction between neurovirulence and neuroinvasiveness is implied from observations on recombinant LACV with mutations in the fusion peptide domain of Gc, which showed reduced replication in muscle cells but retained the ability to cause neuronal loss in culture.⁵⁰¹ The lesions observed in the brains of fatal La Crosse encephalitis cases differ from those in infected suckling mice. In humans, and to a large extent in adult mice infected intracerebrally, cerebral edema, perivascular cuffing, glial nodules, mild leptomeningitis, and occasional areas of focal necrosis that are typical of acute severe viral encephalitis are observed. Lesions are mostly in the cerebral cortex, with some in the brainstem.²⁴³ Studies with Tahyna virus and JCV showed strain differences in neuroinvasiveness and neurovirulence in a Swiss Webster mouse model, whereas in rhesus monkeys no clinical disease was observed but the animals mounted strong neutralizing antibody responses.^{39,40}

Infection of natural vertebrate amplifying hosts of these viruses, such as adult chipmunks (LACV) or snowshoe hares (snowshoe hare virus), results in inapparent infection and viremia sufficient to infect mosquitoes.⁴⁷⁷ *Aedes triseriatus* mosquitoes are the principal vector of LACV, and their experimental infection with California encephalitis serogroup viruses has been studied in detail.^{36,529,535,564} Viruses ingested via a viremic bloodmeal infect the epithelial layer surrounding the mosquito midgut. Replication of the virus results in release of the virus across the basal lamina into the hemocoel, allowing transport of the virus to tissues throughout the body. Virus infection of mosquitoes other than the principal vector species usually results in poor penetration of the virus across this midgut barrier. Experimental infections using reassortant viruses have shown that virus M genomic segment (encoding the glycoproteins and NSm protein) is an important component in the correct match between virus and host mosquito, which allows efficient transit across the midgut barrier.³⁶ Once across the barrier, virus replication occurs in a wide variety of tissues, including the ovaries and salivary glands.⁵²⁹ Release of virus from the salivary glands allows virus transmission from the female mosquito to the vertebrate host during feeding. Mosquitoes begin to be infectious approximately 1 or 2 weeks after ingestion of virus, an interval referred to as the extrinsic incubation period.

The infection of the ovaries is thought to be crucial for virus maintenance in mosquito populations, in that it results in transovarial transmission of the virus from the female to the offspring and allows the virus to overwinter in infected eggs.⁴⁶¹ In addition, LACV-infected females appear to mate more efficiently than uninfected mosquitoes.⁴⁴¹ Male mosquitoes play no role in the vertical transovarial transmission of the virus, or in the horizontal transmission via amplifying vertebrate hosts, as they do not take a bloodmeal. However, the virus is detected in the gonads of transovarially infected males and can result in venereal transmission of the virus horizontally within the mosquito population.⁵³⁵ This combination of transmission mechanisms allows efficient maintenance of the LACV in *A. triseriatus* populations. Similar processes are thought to function in host mosquito infections with other California serogroup viruses,⁵³⁹ and results from studies with these viruses and their arthropod hosts serve as a model for understanding virus maintenance and transmission mechanisms for other family *Bunyaviridae* viruses.

Aino and Akabane virus (AKAV) are important causes of disease in livestock, causing epizootics of abortions and congenital defects in cattle, sheep, and goats.^{201,259,538} Experimental infections of pregnant cattle or ewes with either virus have been shown to produce viremia, followed by virus replication in the placenta and fetal tissues, and resulting in congenital defects such as microencephaly, and hydrocephalus.^{201,286,395,538} Similarly, experimental infection of pregnant hamsters with AKAV results in death of the fetus.¹⁶

Phlebovirus Genus

RVFV pathogenesis and disease has been reviewed in-depth recently.^{54,226,403} RVFV infections of livestock are often recognized by the onset of “abortion storms,” which sweep through livestock-producing areas, with simultaneous acute febrile disease in humans. Most human infections with RVFV result in a mild febrile illness. The incubation period is approximately 2 to 6 days, and is followed by an abrupt onset of fever, chills,

and general malaise. Susceptibility of livestock to RVFV infection varies considerably, depending on a variety of factors, including livestock species and age and the strain of the virus. Based on data from experimental infections and analogy with other arbovirus infections, the general pattern of infection likely follows the same course as that following inoculation of the virus by mosquito bite: the virus is transported by lymphatic drainage to the regional lymph node where local replication takes place. The virus spills over into the circulation, causing the primary viremia and spread of the virus to the major organs. Replication in the lymph nodes, spleen, liver, adrenals, lungs, and kidney tissues results in high viremia, and, in severe cases, hepatic necrosis is prominent and necrotic foci can be observed in the brains of cases exhibiting the less frequent encephalitic form of the disease.³⁵⁵ RVFV replication in cells is highly cytotoxic, suggesting that most cellular destruction in acute illness is likely due to direct virus killing of host cells.

Pathologic features of the disease in livestock vary considerably. Leukopenia is frequently seen during the first 3 or 4 days of infection, when fever and viremia are usually at their highest. Altered serum enzyme levels (e.g., aspartate aminotransferase and sorbitol dehydrogenases) indicative of hepatocyte destruction are often seen during the acute phase. Leukocytosis often occurs in the early phase of recovery. Thrombocytopenia and fibrin thrombi in several organs suggest that disseminated intravascular coagulopathy (DIC) may be a feature of severe disease in livestock, as is seen in hemorrhagic infections in humans.^{107,520}

Infection of pregnant animals frequently results in abortion of the fetus. Abortions early in the course of infection are probably the result of the high fever associated with the acute phase of illness; later abortions are more commonly the result of direct infection of the fetus with resulting hepatic necrosis. No clear correlation between RVFV infection and abortion has been seen in human infections.³⁴⁰

Nairovirus Genus **Vertebrate Hosts**

CCHF and NSD viruses are maintained in nature predominantly in their respective tick hosts. Although the viruses can persist in the ticks through the various life stages (transstadial transmission) and can be passed to the offspring (transovarial transmission), vertebrates are needed to provide blood meals for the ticks, and they can become infected and develop viremia capable of supporting virus transmission to uninfected ticks.¹¹⁵ In this manner, vertebrates may play an important amplifying role in the virus natural cycle. In the case of CCHFV, a variety of livestock (e.g., sheep, goats, cattle, ostriches), large wild herbivores, hares, and hedgehogs may become infected, resulting in an inapparent or subclinical disease.^{210,519} Sheep and goats are implicated as being important vertebrate hosts of NSD virus, and infection often results in severe disease.¹¹⁵ These animals are presumably subcutaneously infected when bitten by infected ticks. Studies of CCHFV pathogenesis have been hampered by lack of a suitable animal model, and most nonhuman primates do show evidence of disease. Recently, two mouse models have been described, one using type I IFN-receptor knockout mice,⁴² the other using Signal Transducer and Activator of Transcription (STAT1) knockout mice⁴¹; the animals are highly susceptible to infection, and the STAT1 knockout mice display many features of human disease including fever, leukopenia, thrombocytopenia, and highly elevated liver enzymes.

In experimental NSD virus infections of sheep, goats, and suckling mice, the virus replicates to high titers in the lung, liver, spleen, and other organs of the reticuloendothelial system.⁵²⁷ Vascular endothelium appears to be the primary cell target. Virus replication in the endothelial cells results in edema and necrosis of the capillary walls of the mucosal surfaces of the intestine, gall bladder, and female genital tract, leading to congestion, hemorrhage, and catarrhal inflammation.

Human Infections

In contrast to the inapparent infection characteristic of CCHFV infection of other vertebrate hosts, human infections often result in severe hemorrhagic fevers. On introduction of the virus, there is likely local replication followed by blood- and lymph-borne spread of the virus to the major organs, including the liver, where high levels of replication take place.⁵¹⁸ Congestion, edema, and focal hemorrhage and necrosis are seen in most organs. DIC is evident early, with thrombocytopenia, elevated prothrombin time ratio and activated partial thromboplastin time (APTT) present during the first few days of illness, and likely plays a central role in disease progression. Little is known regarding host-cell receptor use or factors influencing virus virulence. Both IgM and IgG antibodies are usually detectable approximately 7 days after the onset of illness and are detectable in all survivors by day 9.^{87,158} Antibody responses are rarely detectable in fatal cases.

NSD virus has been isolated from sick patients in Uganda, as has the identical or closely related Ganjam virus from febrile patients in India, but their importance in terms of human disease is currently unclear.

Hantavirus Genus **Reservoirs**

Hantaviruses have been detected in numerous rodents and insectivores (reviewed in 241). To date, all known pathogenic viruses are harbored by rodents, but additional study of the disease potential of the many hantaviruses carried by scrod and talpid insectivores is needed. Hantaviruses are horizontally transmitted among rodents primarily through exposure to excreta and saliva. Infection of natural reservoirs results in an acute phase with high viremia followed by prolonged or persistent infection with variable durations of virus shedding in the urine feces and/or saliva from days to months or even for the life of the rodent. Hantavirus persistence in rodents was found to relate to increased regulatory T cells that modulate the immune response and prevent clearance of infected cells.^{130,131,472} Experimental infection of host rodents indicates that viremia peaks approximately 2 weeks postinfection, and results in dissemination of the virus throughout the animal (e-Fig. 42.9).³⁷¹ The cessation of viremia correlates with the induction of hantavirus-specific antibodies, which first become detectable around 14 days postinfection, peak at approximately 50 days postinfection, and remain detectable for the life of the rodent.³⁰⁴ Although naturally infected rodent reservoirs do not display apparent disease symptoms, reduced winter survival and reduced body weights of infected rodents have been reported.^{95,123,244} Aggressive behavior has been correlated with increased infection among rodents in that the highest seropositive rates are seen in older males and animals with more scars.¹⁷⁹ Hantaviruses appear to target primarily

endothelial cells of rodents, with the highest concentrations of virus antigen being observed in the lungs and kidneys.³⁶⁸

Human Infections

In stark contrast to the asymptomatic hantavirus infection of primary rodent reservoir species, human infections frequently result in HFRS or HPS. Humans are infected by inhalation of aerosols produced from the infected rodent excreta. Virus RNA is usually detectable in patient blood during the early stages of disease. At the time of death, virus antigens are detectable in endothelial cell layers throughout the body, but predominantly in lung endothelial cells in the case of HPS, or kidney endothelial cells in the case of HFRS.^{217,591} Pathologic findings in HFRS patient kidney biopsies include mild to moderate interstitial infiltration of lymphocytes, plasma cells, monocytes/macrophages, and polymorphonuclear leukocytes (mainly eosinophilic granulocytes and neutrophils), although the exact mechanism of kidney failure in HFRS patients is unclear.⁵²⁵ The lung is the primary target organ of HPS. Patients usually develop pulmonary edema, plural effusions, and interstitial mononuclear cell infiltrate, edema, and focal hyaline membranes. Viral antigen is plentiful in lung endothelial cell.^{409,591}

In general, both HFRS and HPS result from capillary leakage and fluid loss. A number of studies have implicated immune-modulated processes rather than virus-induced cell death as the primary cause of disease. Hantavirus-specific antibodies and T cells are detectable at the time of onset of disease symptoms, consistent with immune-pathogenesis (reviewed in 241). For example, in HFRS, the expression of the cytokines tumor necrosis factor α (TNF- α), TGF- β , and platelet-derived growth factor has been observed at the peritubular area of the distal nephron. Similarly, high numbers of cytokine-producing cells can be seen in the lungs (but not the kidneys and livers) of fatal HPS cases, suggesting that local cytokine production may play an important role in pulmonary edema and the high case-fatality rate. Severity of illness in humans has been correlated with specific human lymphocyte antigen (HLA) haplotypes, both HFRS and HPS.^{328,365,548,561}

EPIDEMIOLOGY AND ECOLOGY

Orthobunyavirus Genus

Most orthobunyaviruses are transmitted by mosquitoes, although a few have been isolated from tabanids, phlebotomines, tick, and bedbugs, and have been found in every continent except Antarctica.⁵⁰

California Serogroup Viruses

LACV is the most significant of the California encephalitis serogroup viruses in terms of causing human disease in the United States, with an average of 79 cases per year, predominantly in children younger than 15 years of age. There is, however, severe underreporting.^{195,240} The primary vector is the forest-dwelling, tree-hole-breeding mosquito, *Aedes triseriatus*, although more recently, and concerning, the virus has also been isolated from the aggressive day-feeding Asian tiger-mosquito, *A. albopictus*.²⁹⁰ *A. triseriatus* is found throughout the northern Midwestern and Northeastern United States, and LACV is maintained in these

mosquitoes by transovarial transmission, which allows overwintering of the virus in mosquito eggs.⁵⁶⁵ During the summer months, squirrels, chipmunks, foxes, and woodchucks become viremic following LACV infection, and are important amplifying hosts.^{534,590} The majority of La Crosse encephalitis cases occur in the summer and early fall months when risk of bite from infected female mosquitoes is highest. Historically LACV infections mostly occurred in the Mississippi and Ohio river basins, with more than 90% of cases coming from Wisconsin, Minnesota, Iowa, Indiana, Ohio, and Illinois,⁵⁰ but since the 1980s, more cases have been reported from Appalachia and eastern Tennessee, and between 1987 to 2009 more than 30% of total cases in the United States were from West Virginia.¹⁹⁴

Jamestown Canyon virus (including the closely related Jerry Slough variety) is also associated with arboviral encephalitis in the United States. The virus is vectored by *Culex inornata* mosquitoes, and several species of *Aedes* mosquitoes, and is broadly distributed across much of North America. Vertical transmission of the virus has been demonstrated in several *Aedes* species mosquitoes.¹⁹⁹ White-tailed deer are the most likely vertebrate amplifying host. Unlike LACV, which mainly causes encephalitis in children, Jamestown Canyon virus appears to predominantly cause disease in adults, although only 15 human cases have been reported since 2004.²³

Bunyamwera Serogroup Viruses

Bunyamwera virus is present throughout much of sub-Saharan Africa, and appears to be an important cause of acute febrile illness in humans. The virus has been isolated from humans in Uganda, Nigeria, and South Africa.^{181,271,532} More recently, Ngari virus has been identified as a reassortant BUNV, with its M segment derived from the Batai virus (i.e., S_{BUN} M_{BAT} L_{BUN}). This reassortant virus has been associated with hemorrhagic fever cases in Somalia and Kenya and a large outbreak of acute febrile illness in Sudan.^{58,64,175,587} In addition, human antibodies reactive with BUNV have been detected in most of sub-Saharan Africa, with high prevalence (up to 82%) being recorded in some locations.⁴⁹⁹ Isolation of the virus from several *Aedes* species mosquitoes has implicated them as the primary vector.^{271,499} Antibodies reactive with BUNV have been detected in domestic animals, nonhuman primates, rodents, and birds, and viremias capable of supporting mosquito transmission have been recorded in experimentally infected rodents, bats, and primates.^{499,576} However, the role of a potential vertebrate amplifying host is currently unclear.

Several additional Bunyamwera serogroup viruses are present in the Americas³⁷⁰ and are infrequently reported to cause acute febrile illness in humans. Cache Valley virus is found throughout the United States, Canada, and Mexico, and often infects sheep and possibly all ruminants; infections have been associated with embryonic and fetal death, stillbirths, and multiple congenital malformations in sheep.^{134,337} The virus has caused a fatal encephalitis in a human.⁴⁷⁶ It remains unclear whether Cache Valley and serologically closely related viruses may play a role in syndromes of congenital malformations and embryonic losses in humans in North America.⁷⁵

Simbu Serogroup Viruses

Simbu serogroup viruses are global in distribution, and are principally vectored by biting midges of the genus *Culicoides*. Since the original isolation of OROV from a febrile patient in

Trinidad in the 1950s, the medical importance of the virus, particularly in the Amazon basin regions of northern Brazil and Peru, has become increasingly evident.⁴¹⁸ Between 1960 and 2009, at least 500,000 people are thought to have been infected in more than 30 outbreaks.⁵⁵⁰ Most of these outbreaks were in relatively urban areas, leading to the suggestion that there are likely separate urban and sylvatic cycles.^{121,448}

The principal urban vector in Brazil appears to be the tiny biting midge, *Culicoides paraensis*,^{415,448} which breeds in rotting vegetative matter, and seasonal populations can become high in agricultural areas, where build-up of debris such as banana tree stalks or cacao husks may occur.⁴¹⁷ These midges feed predominantly in the early evening hours and are quite anthropophilic. Infected humans develop viremia sufficiently high to transmit the virus to uninfected midges, and appear capable of serving as the vertebrate amplifying host during urban epidemics.⁴¹⁷ Serologic data also suggest that primates or sloths, or even birds, may be potential hosts in the sylvatic cycle. Recent phylogenetic studies indicate that four distinct OROV lineages are present in different geographic areas, and that OROV emerged in Brazil in around 1790.⁵⁵⁰

AKAV is widely distributed throughout Australasia (Australia, Japan, Korea, Taiwan), the Middle East (occasionally extending as far north as Turkey), and sub-Saharan Africa.^{8,15,111,352,524} The virus is an important cause of disease in livestock, with periodic outbreaks of abortions, stillbirths, and congenital malformations recorded in cattle, sheep, and goats in Australia, Japan, Korea, Taiwan, Israel, and Turkey, although intriguingly no disease outbreaks have been observed in Africa, despite the widespread presence of the virus.⁸ The virus is vectored by midges of the genus *Culicoides*, and although *C. brevitarsis* is the primary vector in Australia,³⁶⁴ different species are important in Asia and the Middle East.^{6,234,285}

Phlebovirus Genus

The geographic distribution of SFSV and SFNV Naples viruses closely follows that of their sandfly host, *Phlebotomus papatasi*.⁵²⁸ This distribution extends from the Mediterranean basin throughout the Middle East and Arabian peninsula, north up into areas around the Caucasus mountains, and as far east as Pakistan and India. Sandflies are most numerous in the warmer months, are found at ground level, and feed in the early evenings. Unfortunately, their small size allows them to pass through untreated mosquito netting.

A related phlebovirus, TOSV, is hosted by *P. perniciosus* and is found in central Italy, Cyprus, Portugal, and Spain. Relatively high (20% to 25%) antibody prevalence rates suggest that human infections with TOSV are widespread and frequent in endemic areas.^{60,136} In addition, many acute lymphocytic meningitis and meningoencephalitis cases, particularly those in children, occurring in the summer months are attributable to TOSV infection.^{59,136,341,374} These viruses replicate in their sandfly hosts, and virus transstadial and transovarial transmission have been demonstrated.⁵³¹ Sexual transmission of TOSV among sandflies has also been shown.⁵³⁰ The relatively low efficiency of transovarial transmission demonstrated in experimental infections suggests that vertebrate amplifying hosts are required to maintain these viruses in endemic areas. However, although antibodies to TOSV are present in many domestic animals, virus isolation has been unsuccessful, suggesting that these animals do act as reservoirs,³⁶⁷ and the identity of

amplifying hosts remains uncertain. Data showing that viremic humans can infect *P. papatasi*, together with attack rates as high as 75% and records of urban outbreaks of sandfly fever, suggest that humans can on occasion serve as the amplifying vertebrate host.⁴⁵⁶

The ecology and epidemiology of RVFV is complex and poorly understood. The geographic distribution of RVFV covers much of Africa, from Senegal to Madagascar and from Egypt to South Africa, with most reported epizootics in livestock being reported in East and Southern Africa.^{288,403} Mosquitoes have long been known to play an important role in RVFV epizootics, with epizootics frequently occurring at times of unusually high precipitation.³¹⁶ More recent data indicate that floodwater *Aedes* mosquitoes of the subgenera *Aedimorphus* and *Neomelaniconion* are likely the principal vectors. The ecology of RVFV has been best studied in Kenya, Zimbabwe, and South Africa. In these regions, damboes or vleis, which are shallow depressions up to several hundred meters across near streams and fed by ground water, are thought to play a central role.⁵¹⁶ These damboes flood at times of unusually heavy rainfall, which triggers a population explosion in floodwater *Aedes* mosquitoes.

Isolation of RVFV from unfed male and female *A. mcintoshi* mosquitoes hatched at a dambo in the endemic area of Kenya during an interepidemic period demonstrated the maintenance of the virus between epidemics and the transovarial transmission of the virus in such mosquitoes.³¹⁷ *A. mcintoshi* is thought to be the principal maintenance vector in Kenya and Zimbabwe.⁵¹⁷ The biology of these mosquitoes is such that they are among the earliest mosquitoes to hatch from eggs following flooding. If the eggs contain virus (via transovarial transmission), infected mosquitoes hatch and feed on nearby livestock, potentially initiating a local epizootic. Viremic livestock act as amplifying hosts that transmit the virus to other floodwater *Aedes*, and also other species of mosquitoes including culicines and anophelines, promoting further amplification and spread of the virus. When such a cycle gets initiated at damboes throughout a livestock producing area, it could give rise to a regional, relatively synchronous eruption of RVFV activity with an associated abortion storm, such as those observed in livestock at various intervals in East and Southern Africa.⁴⁰³ Although such a scenario is an attractive explanation of the dynamics of RVFV epizootics, more data are necessary to confirm this is the case.

Hemorrhagic fever cases in humans are usually seen 1 or 2 weeks after the appearance of abortions and disease in livestock. Cases are usually among farmers and others living in proximity to livestock. Humans likely acquire infection through a bite from an infected mosquito when vector densities are high. However, contact transmission seems to be most important with RVFV. People involved in the birth or abortions of livestock, butchering of animals, abattoir workers, and so on, are at high risk of infection during epizootics.^{2,88} RVFV is also highly infectious by aerosol, having resulted in many infections of laboratory personnel working with the virus.^{161,500} The relative contribution of infectious aerosols or fomites to transmission is unclear. Although less than 1% of human infections result in severe disease (hemorrhagic fever, encephalitis, retinitis), this can add up to a substantial number of cases given the large scale of some epizootics. For instance, an estimated 27,500 RVFV infections occurred during the 1997/1998 outbreak in the Garissa district of Kenya,⁵⁸³ and

approximately 200,000 human cases with 600 deaths were estimated to have occurred during the outbreak in Egypt in 1977 and 1978.³³⁹ The 2008 outbreak of RVFV in Sudan resulted in 698 human cases with 222 deaths, a case fatality rate of 31.8%.⁵⁷⁷ The economic effects of RVFV epidemics are huge, with the 2006/2007 outbreak in Kenya resulting in losses from livestock deaths valued at more than 7.6 million US dollars.⁴⁴⁶

In contrast to the long history of periodic RVFV epizootics in East and Southern Africa, the recent large RVFV outbreaks in Egypt in 1977 and 1978 and in West Africa in Mauritania/Senegal in 1987 were different situations.⁵⁹³ In Egypt, retrospective studies showed that RVFV had not been enzootic prior to 1977.³⁴⁰ Virus activity disappeared after 1981, only to be reintroduced in 1993.²⁸ These data suggest that although mosquitoes capable of acting as epizootic vectors (e.g., *Culex* sp.) exist in Egypt, mosquitoes capable of RVFV transovarial transmission are probably lacking. It is thought that RVFV was most likely introduced into Egypt from enzootic areas in Sudan.³³⁹

The first confirmed RVFV outbreak outside Africa was reported September 2000, in the western coastal plains of Saudi Arabia and Yemen.⁴⁸⁸ Unusually heavy rains and flooding of the foothills of the Asir mountains appeared responsible for increased mosquito populations and the explosive outbreak in naïve livestock. Eight hundred eighty-four hospitalized patients were identified in Saudi Arabia, with 124 deaths. In Yemen, 1,087 cases were estimated to have occurred, with 121 deaths. The virus associated with this outbreak was almost identical to those associated with earlier RVFV epidemics in East Africa, consistent with the recent introduction of RVFV into the Arabian Peninsula from East Africa.⁴⁸⁸ More recent outbreaks in Madagascar have been linked to importations of infected animals from on-going epidemics in East Africa.⁸⁰

Nairovirus Genus

The epidemiology of CCHFV reflects the complex ecology and geographic distribution of the *ixodid* tick hosts of the virus, particularly those of genus *Hyalomma*.^{147,210} Although CCHFV has been isolated from approximately 30 different tick species, evidence is lacking as to whether they truly represent vectors, or merely reflect the isolation of virus from engorged ticks that have fed on a viremic vertebrate host. Only some ticks of three genera, *Hyalomma*, *Dermacentor*, and *Rhipicephalus*, have actually been shown to be capable of transstadial transmission of CCHFV (i.e., passing the virus through the various stages of the life cycle, from larva to nymph to adult) following feeding on a viremic host. Transovarial transmission of CCHFV has also been shown to occur with some of the tick species in these genera. Moreover, the overall global pattern of geographic distribution of CCHFV cases corresponds most closely with the distribution of *Hyalomma* ticks, suggesting their principal role as vector.

There is evidence that CCHFV is present throughout much of sub-Saharan Africa (from Egypt to South Africa, and from Senegal to Madagascar), eastern Europe, the Middle East, and parts of Asia, particularly the former Central Asian republics, and Xinjiang province of NW China.¹⁴⁷ Of note is the emergence of CCHFV in Turkey since 2002,³⁸⁷ which may be related to climate change influencing tick distribution.^{139,558}

Most human infections are acquired by bite from infected ticks, contact with infected ticks during their removal from animals or human body, or contact with blood or tissues of

infected livestock. As one would expect, most cases are among individuals (e.g., shepherds, ranchers, and abattoir workers) living or working in close contact with livestock (e.g., sheep, goats, cattle, or ostriches) in endemic areas. Nosocomial outbreaks have also been reported in several regions, with infection of medical personnel following treatment or surgery on an unsuspected CCHFV case.¹⁴⁷

The distribution of NSD virus mirrors the distribution of the principal tick host, *Rhipicephalus appendiculatus*. The virus is present throughout much of Africa, from as far north as Ethiopia and Somalia, extending through much of East and Central Africa, and as far south as the Mozambique coastal plain.^{114,585} The distribution likely extends through parts of the Middle East and into India, based on the detection of the closely related NSD virus Ganjam variant from *Haemaphysalis intermedia* ticks.¹¹²

Hantavirus Genus

The geographic distribution of hantaviruses and epidemiologic patterns observed for HFRS and HPS reflect the distribution and natural history features of the hantavirus-infected rodent hosts of these viruses. This is because hantavirus infection of the rodent primary reservoir species produces a persistent infection with prolonged shedding of the virus, whereas infection of humans results in an acute infection with quick clearance of virus and recovery in survivors. Epidemiologic data accumulated since the 1950s for a variety of hantaviruses, including HPS-associated hantaviruses, suggest that human-to-human virus transmission does not occur, and that virtually all human infections are acquired by exposure to infected rodent excreta, with the one exception of an ANDV-associated HPS outbreak in Patagonia, Argentina, which clearly demonstrated human-to-human transmission between a patient and her physician, and circumstantial evidence suggested several additional human-to-human virus transmissions during this particular outbreak.^{388,570} This does not appear to be a common property of ANDV, as no health care workers became infected in the course of handling ANDV-associated HPS cases in a subsequent large HPS outbreak in Chile.⁸⁹

HTNV is found in various parts of eastern China and Korea and Far Eastern Russia, and is present in *Apodemus agrarius mantchuricus*, a mouse that is common in agricultural fields. Adults in rural areas (e.g., farmers, forest workers, or troops stationed in the field) are the most at risk of infection, and HFRS cases are seen to peak in the fall. This likely reflects a mixture of factors including the increased abundance of virus-infected mice in the fall coinciding with increased human activity in the fields associated with harvest of crops, and movement of rodents into the houses as winter approaches.²⁹⁹ Most cases are 20 to 50 years in age, and cases in children younger than age 10 are uncommon.^{91,303} A greater number of male than female cases is seen, consistent with predominant exposure being in the fields rather than in the homes. HTNV-related HFRS is probably most important in China, where approximately 100,000 cases are reported each year. A range of 300 to 900 HFRS cases are estimated to occur in Korea each year, and approximately the same number of cases are thought to occur in Far Eastern Russia annually.

SEOV is associated with the domestic rats, *R. norvegicus* and *R. rattus*,^{305,514} and is worldwide in distribution due to the recent global spread of rats to port cities and beyond through

international shipping.³⁰⁰ Seoul is the only hantavirus known to cause disease in urban areas, as the other hantaviruses are associated with rodents that are predominantly rural in their distribution. SEOV-related HFRS cases appear to be rare outside of China and Korea and institutions housing laboratory rat colonies, the exact reason for which is unclear. SEOV-related HFRS cases in general tend to be more moderate than those associated with HTNV, although mortality rates still range up to approximately 1% to 5%. Although most cases are in cities, SEOV-related HFRS cases are also seen in some rural areas in China. The seasonality of SEOV-related outbreaks are different from HTNV-related HFRS, with most cases occurring in spring and early summer as opposed to fall and early winter.⁹² The annual number of cases is unknown, as figures for SEOV- and HTNV-related HFRS are often not separated. However, Chinese reports suggest that SEOV-related HFRS in urban areas of several provinces has been on the increase since its discovery in 1981.⁹⁰ A genetically related virus, Thailand virus, is found in *Bandicota indica* rodents in Thailand, but is not known to cause human disease.

In Europe and Scandinavia most cases of HFRS are caused by infection with PUUV. Particularly in Scandinavia, disease is referred to as Nephropathia epidemica (NE). NE is usually milder than HTNV-associated HFRS. The virus is hosted by the bank vole, *Myodes glareolus*. In Sweden and Finland, the number of cases in rural residents usually peaks in November and January, although cases in urban residents appear to peak in August, which likely correlates with vacationing in summer cabins in rural areas. A male-to-female case ratio of approximately 2:1 is seen, and the disease is rare in children.⁶⁷ Local epidemics usually reflect increased local bank vole densities, which tend to cycle with a 3- to 4-year periodicity. Approximately 30% of PUUV infections result in reported disease, based on data from areas of Finland with high surveillance for disease.⁶⁷ In addition, antibody prevalence rates of up to 20% can be seen in known endemic areas in northern Sweden.²¹² Hantaviral disease in Belgium, northeastern France, and Germany occurs mainly in autumn and spring, and the extent of activity reflects the alterations in the size and structure of bank vole communities.⁴¹⁴ Large PUUV-associated HFRS outbreaks are periodically recorded in several areas of European Russia, particularly Udmurtia and Bashkortostan. A genetically distinct PUUV-like virus has also been identified in *C. rufocanus* voles in Far Eastern Russia and on Hokkaido Island, Japan, but is not known to be associated with human disease.²⁴⁸ Several additional hantaviruses are known to be associated with other subfamily *Arvicolinae* rodents but are not known to cause human disease. Topografov virus is present in lemmings in Arctic regions of Russia, and at least five hantaviruses are associated with various Old and New World rodents of the *Microtus* genus.

Dobrava virus (DOBV) also causes a considerable number of severe HFRS cases in Europe, particularly in the Balkan countries.^{30,392} The primary rodent reservoir is *A. flavicollis*, which is widely abundant in this region. However, a variant of DOBV, Saaremaa virus, can be found in *Apodemus agrarius* (a subspecies distinct from that which carries HTNV in Asia), which is of greater abundance in more northern areas.⁴⁹⁶ Although *A. flavicollis* does not frequent houses and other manmade structures, it will often enter campsites or places where food may be present. Unlike HTNV-associated HFRS, most DOBV-

associated HFRS cases occur in the late spring and summer months when activity in the rural areas is greatest. Epidemics of disease are seen at times when rodent populations are high, and have also been noted to increase in years when military conflicts are ongoing.³²⁵ Seroprevalence rates can be high in rural areas; for instance, antibody positivity rates of up to 14% were seen in mountainous areas of northern and western Greece.²⁴

Since the discovery of SNV and HPS in 1993, numerous other hantaviruses have been detected in New World subfamily Sigmodontinae rodents. In North America, SNV is by far the most important cause of HPS.³⁵³ SNV is present in deer mice (*P. maniculatus*, grasslands form) throughout Western and Central United States and Canada.³⁵³ The initial 1993 cluster of HPS cases occurred in the Four Corners region (meeting point of New Mexico, Arizona, Colorado, and Utah), and the majority of subsequent cases have been identified in the southwestern United States. However, HPS cases have now been identified in 32 states in the United States and four provinces of Canada, and SNV-infected deer mice have been detected throughout most of its range, which stretches from the Yukon to Mexico and from California to the Appalachian mountains in the eastern United States and Canada.^{343,353} Through December 2010, a total of 560 cases of hantavirus pulmonary syndrome have been reported in the United States with a case fatality rate of 36%. A survey of 2,500 individuals in risk groups, such as those with occupations that would bring them in close contact with rural rodents, found hantavirus-specific antibodies in only approximately 0.5% of those sampled,^{556,592} suggesting infection of humans with SNV is rare. It appears that clusters of cases are generally associated with local increases in infected deer mice populations. The peak of HPS cases occurs late spring–early summer, and as of December 2009, in the United States, 63% of cases have been male and 37% female and the mean age of patients is 37 years (range 6 to 83 years). Retrospective studies suggest the disease had gone unrecognized since at least 1959.¹⁶⁰ Several other hantaviruses are capable of causing HPS in the United States. The forest form of deer mice (*P. maniculatus nubiterrae*), which are found predominantly throughout the Appalachian mountain range extending from Georgia to eastern Canada, harbor a genetically distinct SNV-like virus referred to as Monongahela virus.^{353,503} This virus has been associated with several HPS cases in the Eastern United States. The white-footed mouse, *P. leucopus* (eastern haplotype) hosts another SNV-like virus, named New York virus. This virus has been responsible for some HPS cases in the Northeastern United States.^{208,213} A different hantavirus, Blue River virus, is present in *P. leucopus* (western haplotypes), in the Central and Western United States, but this virus is not known to be associated with human disease.³⁵⁸ Mitochondrial DNA analysis of the different rodent hosts shows that each of these rodent hosts is genetically distinct.³⁵⁸ This is in keeping with the general pattern for hantaviruses, whereby each specific hantavirus is hosted by a single different species or subspecies of rodent, and each specific rodent species or subspecies serves as the primary reservoir for only a single specific hantavirus.^{371,422}

Other sigmodontine genera harbor HPS-associated hantaviruses in the United States, such as BCCV, which was associated with a single HPS case in southern Florida and is hosted by the cotton rat, *Sigmodon hispidus* (eastern form).⁴³⁸ The genetically distinct western form of *S. hispidus* hosts a genetically distinct hantavirus, Muleshoe virus.⁴³⁹ Bayou virus

was discovered in 1994, associated with a fatal HPS case in Louisiana.³⁵⁷ Subsequently the virus was shown to be hosted by the rice rat *Oligoryzomys palustris*, to be present throughout the range of the rodent,²⁷⁹ and associated with a nonfatal HPS case in Texas.²⁰⁶ Although the HPS associated with BCCV and Bayou virus is still predominantly a pulmonary disease, there does appear to be more renal involvement than seen in classic SNV-associated HPS.^{206,256}

The confirmation of an HPS case in Brazil in late 1993 marked the beginning of a wave of discovery of HPS cases and associated hantaviruses throughout South and Central America. In addition to Brazil, Argentina, Bolivia, Brazil, Chile, Ecuador, Paraguay, Panama, Uruguay and Venezuela have also reported HPS. Rodents carrying viruses similar SNV have been found in Colombia, Costa Rica, and Mexico, but have not been associated with disease in humans.

The finding of high prevalence of hantavirus-specific antibodies in the general population in some areas of South and Central America differs considerably from the epidemiologic picture seen in North America, where seropositivity rates of 0.2% or less are seen. For instance, high rates of hantavirus-specific antibodies have been seen on surveillance of general populations in regions of Paraguay (40%), Salta province in Argentina (17%), and Los Santos province in Panama (13%).^{152,581} These data suggest more frequent exposure of people to hantaviruses in these areas and more inapparent or subclinical infections than seen with North American hantavirus infections.

Phylogenetic analysis of hantaviruses and their rodent reservoirs have indicated that their evolutionary trees overlap with only a few exceptions, suggesting that these viruses have co-evolved with their rodent hosts over 20 to 30 million years.^{371,373,422} These data show that although HPS and many hantaviruses were only recently discovered, they are actually quite ancient.

CLINICAL FEATURES

Orthobunyavirus Genus

The California serogroup viruses, LACV, Jamestown Canyon, and the prototype California encephalitis virus, all cause a similar encephalitic disease in humans.⁴⁵³ Indeed, due to serologic cross reactivity, many of the early disease descriptions of California encephalitis cases were likely due to Jamestown Canyon virus or LACV rather than California encephalitis virus, which is now known to be less common.^{76,120} The major difference between the viruses is in age-dependence of the spectrum of clinical disease observed, in that LACV infections tend to be more severe in children, whereas Jamestown Canyon virus infection is more severe in adults. The spectrum of disease ranges from inapparent or mild febrile disease through to fatal encephalitis.^{101,338,536}

The incubation period is approximately 3 to 7 days. Most cases report sudden onset of fever, followed by stiff neck, lethargy, headache, and nausea and vomiting, and symptoms usually end within 7 days. Approximately half the cases exhibit seizures, and up to 30% develop coma and exhibit a longer disease course. About 65% of patients have meningitis on presentation, with both mononuclear and polymorphonuclear cells present in cerebrospinal fluid. Despite mild neurological symptoms often present at the time of patient discharge, surprisingly

little residua is found. The most important sequela is epilepsy, which is observed in approximately 10% to 15% of children, and these are almost always patients who had seizures during acute phase of illness. In addition, about 2% of patients have persistent paresis.^{101,194,338}

Several thousand cases of acute febrile illness can occur during Oropouche virus epidemics observed throughout the Amazon basin regions of Brazil and Peru. Humans acquire the infection by bite from infected midges. The incubation period is approximately 4 to 8 days, followed by sudden onset of fever, with arthralgia, myalgia, severe headache, chills, photophobia, and prostration. Occasionally, rash, meningitis, or meningismus are seen.^{359,416} Most of the symptoms resolve within 3 to 5 days, although the myalgia may last 1 or 2 weeks. Viremia is detectable in the majority of patients 2 to 3 days after onset of illness. Approximately half of the patients can exhibit recurrence of some disease symptoms 1 to 10 days after initial recovery.⁵⁴⁹ Oropouche virus is also suspected to be infectious by aerosol, based on reported laboratory infections.⁴¹⁸

Phlebovirus Genus

Human infections with sandfly fever viruses results in an acute febrile illness with rapid onset. The incubation period last 2 to 6 days, followed by fever and general malaise, often accompanied by headache, photophobia, and back and joint pain.^{34,456} The disease is self-limiting, lasting 2 to 4 days before rapid and complete recovery.

Experimental RVFV infection of newborn lambs and kids suggests that the incubation period is usually 24 to 36 hours, but can be as short as 12 hours.¹³² Fever, which is often biphasic, is accompanied by listlessness, lack of appetite, abdominal pain, increased respiration rate, and lack of movement. Mortality rates of greater than 90% can be seen in animals younger than 1 or 2 weeks of age, with animals rarely surviving beyond 24 to 36 hours after onset of illness. Older lambs and kids, and adult sheep and goats are often less susceptible to RVFV infection, ranging from peracute to inapparent infection. Most older animals develop a febrile acute illness similar to the disease seen in 1- to 2-week-old animals, but with morality ranging from 5% to 60%, and a longer incubation period of 1 to 6 days. High and prolonged viremias, widespread tissue damage, vasculitis, and hepatic necrosis are seen in the more severe cases. Abortions in pregnant animals are frequently observed, with rates varying from 40% to 100%.

Human infections rarely lead to severe illness, with most infections resulting in a self-limiting influenza-like illness. However, approximately 0.5% of infections lead to severe hemorrhagic fever. In such cases, it is likely that the reduction of the antithrombotic function of the endothelial cells initiates intravascular coagulation and extensive necrosis of hepatocytes and other infected cells. The release of procoagulants into the circulation, together with the extensive liver damage, which severely impairs synthesis of coagulation factors and removal of circulating activated coagulation factors, are likely important factors resulting in DIC in the hemorrhagic fever cases.^{406,407}

In less than 0.5% of human RVFV infections, retinal vasculitis or encephalitis can be observed 1 to 4 weeks after recovery from the acute illness. Encephalitis begins with headache, meningismus, and confusion. Often fever reappears, and symptoms of severe cases include hallucinations, stupor, coma, and death. Focal necrosis, which most likely involves direct cell

destruction by the virus, is seen in the brain. In addition, that the onset of encephalitis after viremia has ceased and RVFV-specific antibodies are readily detectable suggests that there may be an immunopathologic component to these late complications.⁴⁰⁵ Indeed, polymorphonuclear and mononuclear cell infiltration associated with necrotic lesions implicates delayed hypersensitivity or cytotoxic T cells.⁴⁰⁵

Nairovirus Genus

The incubation period for CCHFV infections is commonly 3 to 7 days, but it varies depending on type of the exposure. Symptoms usually appear abruptly, and can include severe headache, dizziness, nausea, fever, neck and abdominal pain, and chills. Overall myalgia and malaise occur, and hepatomegaly may be seen. Hemorrhage frequently appears by 3 to 6 days postonset of illness, with a petechial rash observable on the trunk and limbs. Patients are often apathetic or obtunded by this stage, with delirium or coma occurring in the more severe cases. Blood may be seen in the urine, and bleeding from the nose, gums, vagina, and other mucosal surfaces or needle puncture sites may occur approximately 5 days after onset. The case fatality rate is approximately 30%, with most deaths occurring 5 to 14 days after onset of illness.^{147,518,572}

Hantavirus Genus

Severe HFRS begins with a phase lasting for 3 to 5 days typified by high fever, headache, malaise, chills, and prostration. Flushing of the face and neck, and conjunctival and pharyngeal injection (indicating capillary dilation) are frequently observed. Increased capillary permeability is likely responsible for the retroperitoneal edema and lower back pain often described. This febrile phase is followed by a hypotensive phase lasting several hours to days, characterized by marked thrombocytopenia, and often by petechial hemorrhage. Many patients exhibit low-grade DIC, and approximately 10% to 15% of patients show some degree of shock around this time. Usually shock improves within 12 to 48 hours and blood pressure returns to normal, or the patient becomes hypertensive. Oliguria may occur, and, historically, renal failure contributes to about half of the deaths.¹²⁹ Recovering patients will then go through a phase of diuresis that may last several months. Obviously, not all patients go through all the stages described, with some of the more severe cases rapidly progressing through to death in a few days, whereas other cases will skip some phases of the disease or exhibit very mild symptoms and not be recognizable as HFRS. However this tends to be the most severe form of HFRS, with a 5% to 15% case fatality. SEOV-associated HFRS tends to be milder, with a mortality rate of 1% or 2%. In general, the disease course resembles that observed with milder HTNV- and DOVB-associated cases, although more prominent liver involvement often occurs.²⁶⁰ PUUV-associated HFRS (often referred to as NE), is the mildest form of the disease, with a mortality rate of less than 1%. The phases of the illness are generally less pronounced, and symptoms are milder, with hypotension rather than shock, petechiae instead of more frank hemorrhage, and relatively mild renal involvement.

Similar to HFRS, in HPS there is also a 2- to 3-week incubation period followed by rapid onset of acute disease. The first 4 days often include fever, myalgia, malaise, headache, and gastrointestinal symptoms. Patients frequently present for medical attention with the onset of pulmonary edema, dyspnea, and

hypoxemia. These features, together with the hemoconcentration that is frequently observed, are presumably linked to the hantavirus infection of the microvascular endothelial cells surrounding the lungs, which leads to increased permeability and fluid leakage into the lungs. Bilateral pulmonary infiltrates are often visible on chest x-rays. Deterioration of patient condition is often rapid, with death occurring in almost 50% of the cases within 1 to 3 days of hospital admission. Clinical laboratory tests frequently reveal thrombocytopenia and prolonged PTT. Hypotension and shock can be prominent at this stage. Recovery of surviving patients is often remarkably quick, with rapid resolution of the lung lesion and shock within 3 to 6 days. Very similar clinical pictures are seen with HPS cases associated with other viruses found in rodents of the subfamily *Sigmodontinae*. HPS cases have also been associated with SNV-related Monongahela, and New York viruses, Bayou virus, BCCV, ANDV, and related viruses Oran, Lechiguana and Hu39694, Laguna Negra, Juititaba, Araraquara, and Castelo dos Sonhos. The clinical picture seen in HPS cases associated with the BCCV and Bayou viruses differs slightly, in that more renal involvement and elevated serum creatine phosphokinase observed. Renal failure also appeared to be common with Oran virus-associated HPS in northern Argentina.³¹⁰ Flushing and petechiae and frank hemorrhage were seen in some HPS patients infected with ANDV in Argentina and Chile, respectively.²²

DIAGNOSIS

Orthobunyavirus Genus

A wide variety of assays have been used in the diagnosis of infections with viruses of the genus *Orthobunyavirus*, including complement fixation (CF), hemagglutination inhibition (HI), neutralization (NT), immunofluorescence assay, IgM capture enzyme-linked immunosorbent assay (ELISA), and reverse transcriptase-polymerase chain reaction (RT-PCR).^{74,128,186,284,293,428} Diagnosis of California serogroup virus infections relies on serologic methods, as the virus is generally absent from blood or secretions during the phase of CNS disease. The HI test is considerably more sensitive for these viruses than CF, but NT assay or RT-PCR coupled with multiplex nucleotide sequencing²⁹¹ is need for confirmation and subtype identification. The IgM capture ELISA works well for diagnosis of most infections by viruses of the genus *Orthobunyavirus*, but has not been widely applied to date.^{128,219,476} Virus isolation attempts complement serologic and genetic assays, and is best achieved by intracerebral (i.c.) inoculation of suckling mice or infection of susceptible cells such as Vero cells.

Phlebovirus Genus

Sandfly fever should be suspected when patients present with a classic “3 day fever” in areas where phlebotomine sandflies are numerous.^{136,456} Similarly, TOSV infection should be suspected in patients with acute CNS disease during the summer months in rural or semirural areas where phlebotomine sandflies are present.^{60,374} Diagnostic confirmation using acute or early convalescent phase samples is readily achieved by virus isolation by i.c. inoculation of suckling mouse or susceptible tissue culture cells, or IgM capture ELISA.

Differential clinical diagnosis of RVFV varies depending on the region in question. The disease should be suspected in

RVFV-endemic regions following abnormally high precipitation, increased rates of abortion in livestock, and appearance of acute influenza-like illness in persons in close contact with potentially infected livestock (e.g., farmers, veterinarians, and abattoir workers). Virologic diagnosis is usually simple given the high viremia present throughout the acute phase of illness and the ease of growth of the virus when inoculated i.c. into suckling mice, or in a wide variety of susceptible tissue culture cells.⁵¹⁸ Serologic testing is also straightforward, particularly if paired sera (one taken acute and the other 1 or 2 weeks later) are available. IgM and IgG ELISA tests using inactivated RVFV-infected cell lysates or slurries have proven particularly useful in outbreak investigations.^{278,356,547,583} RT-PCR protocols have also been developed, although their utility in clinical settings requires further investigation.⁵⁶⁹

Nairovirus Genus

Clinical differential diagnosis of CCHFV varies in the different regions where the disease is known to occur and can be difficult in early stages. In general, the disease can be suspected for patients presenting with a rapid onset of severe influenza-like symptoms, and known exposure to tick bite or contact with blood or tissues of potentially infected livestock or humans. The early stages can be confused with sandfly fevers in regions where the diseases overlap, and leptospirosis, Omsk hemorrhagic fever, other viral hemorrhagic fevers (yellow fever, HFRS, Ebola), tick typhus, and mycotoxicoses can appear similar in the more advanced hemorrhagic phase of the illness. Clinical values can be helpful in diagnosis, with leukopenia and thrombocytopenia both frequently being present early in the disease.^{147,518}

Rapid laboratory diagnosis of CCHFV can be achieved by RT-PCR,^{70,124} but virus isolation or antigen detection ELISA from patient acute phase sera^{69,147} are also performed. The virus and antigen are usually detectable up to 1 to 2 weeks after onset of illness. For CCHFV isolation, i.c. or intraperitoneal inoculation of patient acute phase blood samples into newborn mice is probably most sensitive, although quicker results can be obtained by inoculation into susceptible tissue culture cells, such as LLC-MK2, Vero, and baby hamster kidney (BHK)-21 cells, followed by fluorescent antibody staining.⁴⁷⁸ Fatal cases rarely show significant antibody responses. However, in those destined to survive, IgM and IgG antibodies are frequently detectable after about a week of illness.

Hantavirus Genus

Clinical differential diagnosis of HFRS and HPS cases can be difficult due to the nonspecific early symptoms in both types of cases. In areas of China, Korea, Far Eastern Russia, Europe, and Scandinavia where HFRS is known to occur, a febrile patient presenting with thrombocytopenia and renal symptoms should be questioned about potential rodent exposure and tested for evidence of hantavirus infection. The early signs of severe HFRS can be easily confused with those of leptospirosis, typhus, pyelonephritis, poststreptococcal glomerulonephritis, an acute abdominal emergency, or other hemorrhagic fevers. Mild HFRS can be confused with hepatitis A, mild leptospirosis, streptococcal pharyngitis, influenza, or nonsteroidal anti-inflammatory toxicity.

In the Americas, the early stages of HPS are extremely difficult to recognize, being easily confused with influenza.

However, fever and myalgia and a history of potential rural rodent exposure, together with the appearance of shortness of breath, and findings of thrombocytopenia, leukocytosis with left shift (higher ratio of immature-to-mature neutrophils), and atypical lymphocytes would be strongly suggestive of HPS.³⁷⁶

Antibodies are invariably seen in patient sera around the time of onset of illness. Laboratory analysis of the presence of virus-specific antibodies has historically included indirect fluorescent antibody (IFA) testing. This has good sensitivity, and hantavirus cross-reactivity and use of a representative virus from each of the main rodent subfamilies harboring hantaviruses (i.e., *Murinae*, *Arvicolinae*, and *Sigmodontinae*) will identify infections caused by virtually all hantaviruses. However, false positives are not uncommon, due to rheumatoid factor problems and overall nonspecific “stickiness” of some patient sera. Some of these difficulties can be controlled for by the inclusion of appropriate negative antigens to detect and remove the effects of problem sera. Although of some utility for acute diagnosis, the inherent nonspecific background and subjectivity problems make the IFA test unsuitable for serologic survey studies. Acute diagnosis is best achieved by IgM capture ELISA using hantavirus-infected cell slurry as antigen and incorporating an uninfected cell slurry control.²⁸⁰ The use of recombinant nucleocapsid proteins with appropriate negative control protein fractions have also proved useful as antigens in this assay format.^{137,151,185} Such assays have been shown to be highly sensitivity, rapid, and inexpensive. Considerable cross-reactivity among related hantaviruses is seen, such that inclusion of a limited number of representative virus antigens (e.g., SNV, PUUV, and HTNV) allow detection of virtually all acute hantavirus infections. The disadvantage of the cross-reactivity of the assay is the inability to precisely identify the virus based on a positive result. Western blot assays utilizing recombinant nucleocapsid proteins or GPs have also been effectively used for acute diagnosis, particularly with New World hantaviruses, and can provide additional insights into virus identity.^{207,233}

Virus isolation attempts from acute clinical specimens are almost always negative. The exact reason for difficulty of isolation of hantaviruses is unknown, but it is likely related to the presence of a strong immune response at the time of onset of illness, including serum-neutralizing antibodies. Demonstration of the lack of amino acid substitutions during the isolation of Sin Nombre virus from infected lung material would suggest that virus adaptation to growth in tissue culture is not a major element in the difficulty of isolation of these viruses.⁹⁷ Given the frequent difficulty in obtaining infectious virus, RT-PCR assay has been used effectively to complement immunodiagnostic assays and allow detailed genetic comparison of the hantaviruses.^{320,373,392,468} Given the potential for false positives due to cross-contamination, RT-PCR is not recommended as the sole means of hantavirus diagnosis.

PREVENTION AND CONTROL

Orthobunyavirus Genus

Prevention and control is difficult for the mosquito-borne California and Bunyamwera serogroup viruses due to the widespread presence of the mosquito vector hosts and relatively sporadic nature of the associated human or livestock diseases. No vaccines are available for human-infecting orthobunyaviruses.

Broad application of insecticides, as carried out in earlier decades, is no longer ecologically acceptable. Relative to human disease, use of fine mesh netting and personal protectants containing N,N-diethyl-meta-toluamide (DEET) are highly recommended in areas with high risk of people being bitten by virus-infected mosquitoes.

Similar vector control challenges exist for the Simbu serogroup viruses vectored by *Culicoides* midges. With the Oro-pouche virus disease in Brazil and Peru, avoiding the build-up of rotting organic debris such as banana tree stalks or cacao husks in agricultural areas may help curtail population levels of *C. paraensis* and reduce the risk of seasonal epidemics.⁴¹⁷ Avoiding exposure (treated netting, DEET repellents) to these midges during their early evening feeding hours is also recommended. Similar protective measures are recommended for AKAV. In addition, a successful formalin-inactivated AKAV vaccine has been developed in Japan using virus-infected hamster lung cell cultures,²⁸⁷ and a trivalent-inactivated vaccine protective against AKAV, Aino virus (AINOV), and Chuzan orbivirus has been successfully trialed in Korea.²⁵⁹ With knowledge of the distribution and seasonality of AKAV disease outbreaks, vaccination of at risk animals prior to pregnancy is feasible.

Phlebovirus Genus

The sandfly hosts of SFSV, SFNV, and TOSV have short flight range, and locomotion is often by hopping, making localized use of insecticide sprays particularly effective around residences. In addition, the use of repellants and treated bed nets and screens is recommended in such areas.

Immunization of livestock remains the most effective way to prevent RVFV epizootics and human cases. Several vaccines exist. Live attenuated viruses based on the mouse neuroadapted Smithburn RVFV strain are used in Kenya and South Africa.^{78,498} Formalin-inactivated wild-type viruses have also been used in Egypt and South Africa.¹³⁸ The modified live Smithburn vaccine has good efficacy in sheep (but not cattle), with a single dose inducing lasting immunity in sheep 6 to 7 days after vaccination.¹⁰² However, it appears to be only partially attenuated, causing abortions or teratology in some pregnant animals.^{223,289} The formalin-inactivated vaccines are safer, but are expensive and induce only short-lived immunity in sheep and cattle. Other candidate live-attenuated vaccines such the mutagen-derived MP12 strain, the naturally occurring clone 13 (which has a large deletion in NSs), and genetically engineered recombinant viruses lacking NSs protein, and perhaps also NSm, are in various stages of evaluation.^{54,223,289,403} Other approaches include DNA vaccines, nonreplicating virus-like particles and subunit vaccines. The main livestock vaccination problem is the long periods between epizootics and their irregular appearance, which makes it difficult to convince livestock owners to vaccinate regularly. Recent advances in the use of satellite imagery and surface ocean temperatures to predict regions at higher than usual risk of RVFV activity, may allow the timely vaccination of animals prior to potential epizootics.^{25,316,554}

In an African setting, humans are probably best protected by vaccination of livestock to prevent amplification of virus, thus limiting human exposure and epizootic potential. Formalin-inactivated RVFV vaccines have been developed for immunization of laboratory and field workers at risk of exposure^{223,288} but are unlikely to be used on a larger scale, given their limited commercial potential. RVFV is highly infectious by aerosol, as

shown by numerous infections of laboratory personnel. Workers at risk of exposure wear protective clothing to avoid contact with potentially infectious materials and aerosols. The antiviral drug ribavirin may be of some benefit in the treatment of sandfly fevers and RVFV, although human efficacy data are still lacking.^{108,408}

Nairovirus Genus

The best means of prevention is to minimize exposure to the virus. Treatment of clothing with pyrethroid preparations, which repels and even kills ticks, is highly recommended for those persons likely to come into contact with CCHFV-infected ticks (e.g., slaughterhouse workers, sheep shearers, veterinarians, and others involved with livestock). In addition, habits that avoid virus-contaminated blood or tissues contacting the skin should be practiced (e.g., wearing of gloves and avoiding crushing ticks with fingers). Medical personnel should practice standard barrier-nursing techniques during care of suspected CCHFV patients. Formalin-inactivated vaccines have been prepared from virus-infected suckling mouse brains and used in Bulgaria and other parts of Eastern Europe and the former Soviet Union, but their efficacy is currently unclear.²⁵³

Treatment of patients is by means of supportive and replacement therapy with blood products. Administration of immune plasma has been tried on numerous occasions, but its usefulness remains unclear. Based on the susceptibility of the virus in experimental tissue culture and mouse infections to the antiviral drug ribavirin, several CCHFV cases have been treated with ribavirin and shown encouraging results.^{147,253}

Hantavirus Genus

The primary means of prevention is the reduction of rodent exposure. Effective measures include rodent-proofing of homes, correct storage of food, airing of seasonally closed cabins, and disinfection and removal of trapped rodents and rodent droppings.^{85,86,180} The lack of nosocomial transmission or person-to-person transmission reported for virtually all hantavirus outbreaks suggests that spread to medical personnel or contacts is usually not a concern. The one exception is the limited person-to-person spread that can occur during ANDV-associated HPS outbreaks.^{388,570}

Several different inactivated virus vaccines for HTNV and SEOV have been developed in Asia.²¹¹ These include virus-infected rodent brain-derived antigens inactivated with formalin or beta-propiolactone.^{302,586} Although such products would not be suitable for use outside the region, good efficacy has been reported.²¹¹ Several monovalent and bivalent HTNV- and SEOV-tissue culture-derived inactivated vaccines have also been produced in China,²¹¹ some of which may have high efficacy. In addition, a number of recombinant DNA approaches to vaccine development have been investigated, some of which show promise in experimental systems (reviewed in 464). Of these, the only study in humans to date was with DNA vaccines for HTNV and PUUV delivered by gene gun, which showed both vaccines to be immunogenic when delivered alone or in combination (C. S. Schmaljohn, unpublished). The sensitivity of HTNV to the inhibitory effects of the antiviral drug ribavirin on virus replication in tissue culture or in animal models²¹⁵ has promoted clinical trials both with HFRS patients and HPS patients, with positive results reported in the case of HFRS.^{214,452}

TOSPOVIRUS GENERAL FEATURES

In infected plant cells, several types of aggregates of virus proteins are observed, and mature virus particles accumulate in the endoplasmic reticulum.²⁶³ Although the spread of virus from plant to plant is by ingestion of the cell contents by thrips, acquisition of a virus envelope membrane containing the virus GPs is still thought to be important for virus transmission by thrips. However, once inside the plant, complete virus maturation may be less critical as movement from cell to cell likely involves virus nucleocapsid movement through plasmodesmata cytoplasmic channels.^{275,510} In addition to the structural proteins, nucleocapsid (N), glycoproteins (Gn and Gc), and RNA polymerase (L), the tripartite genome of these viruses encode two nonstructural proteins, one from the S genome segment, NSs, and one from the M segment, NSm.²⁷³ The NSs protein accumulates in the salivary gland of infected thrips, suggesting a role in virus transmission.⁵⁷⁹ The NSm associates with virus nucleocapsids and localizes to plasmodesmata, where it forms tubular structures thought to be involved in virus cell-to-cell movement.^{275,510}

In contrast to the other arthropod-borne members of the family *Bunyaviridae*, adults of the vector thrips do not acquire the virus, only larvae becoming infected when feeding on virus-infected plants.^{541,575} Infected male *F. occidentalis* thrips were shown to feed more actively than uninfected thrips, thus increasing the opportunities for virus transmission.⁵⁰⁶ TSWV has been shown to be trans-stadially transmitted through molting, pupation, and emergence to the adult stage, and both larvae and adults can transmit the virus to plants.⁵⁷⁸ Unlike many of the other arthropod-borne bunyaviruses, there is no evidence of transovarial transmission for any of the tospoviruses. This presumably reflects the widespread and year-round replication of thrips in most climates and the enormous number of susceptible plants, making vertical transmission of the virus in the vector thrips of lesser importance.

Control of tospovirus infections in a field setting is difficult due to problems in eliminating thrips and the fact that many weed species surrounding cultivated fields will serve as a virus reservoirs. Several breeding programs have attempted to increase natural host resistance of plants to tospovirus infection, but with little success to date.⁵⁰⁸ Attempts to create genetically engineered host-plant resistance are showing promising results and have been reviewed in detail recently.²⁷²

PERSPECTIVES

Although unified by shared characteristics such as tripartite ssRNA genome, virion composed of four structural polypeptides, and cytoplasmic site of replication, the bunyaviruses exhibit considerable diversity in RNA and encoded protein sequences, their genome expression strategies, and biological properties. The degree of understanding of different bunyaviruses varies greatly, dependent on their clinical, veterinary, or agricultural importance, or ease of handling. The family affords considerable research opportunities for the future, three of which are considered of immediate importance highlighted in the following. (a) Large scale sequence analyses of bunyavirus genomes to begin to understand their relationships and evolution, with practical implications for robust classification and improved diagnostics. (b) The development of reverse genetic systems that allow rescue of infectious hanta-,airo-, and tospo-

viruses, which will enhance the pace of research on these viruses (as evidenced from progress with orthobunya- and phleboviruses for which the technology is well-established) and should provide new opportunities in the generation of vaccine and antivirals. (c) An understanding of how bunyaviruses persist in either their arthropod or rodent hosts. What are the cellular interactions that occur that permit efficient viral replication without damage to the host or clearance from it?

Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

Visit Lippincott Williams & Wilkins on the Internet: at LWW.com. Lippincott Williams & Wilkins customer service representatives are available from 8:30 am to 6 pm, EST.

Stephen E. Straus, 1946–2007

Steve Straus was the consummate physician–scientist with broad interests in the basic science and clinical aspects of viral and immunological diseases and therefore was an ideal person to serve as clinical virology editor for *Fields Virology*. We were fortunate to work with him in his role as associate editor for the third through fifth editions of *Fields Virology*. However, unfortunately, with Steve's premature death in 2007, we lost our friend, colleague, and fellow editor. Steve's medical training and accomplishments are detailed elsewhere (*J Infect Dis* 2007;196:963–964). His research interests were broad and included the molecular biology and pathogenesis of varicella-zoster and herpes simplex viruses, acyclovir suppression of oral and genital herpes simplex viruses, antiviral drug resistance, clinical testing of herpes simplex virus and varicella zoster virus vaccines, chronic active Epstein–Barr virus, chronic fatigue syndrome, and autoimmune lymphoproliferative syndrome. Steve was one of the leading scientists in the National Institutes of Health intramural program, serving as chief of the Laboratory of Clinical Investigation at the National Institute of Allergy and Infectious Diseases and the founding director of the National Center for Complementary and Alternative Medicine.

Steve cowrote the chapter on varicella zoster virus, and additionally worked effectively as an associate editor, for the third to fifth editions of *Fields Virology*. He seemed to read and edit the chapters immediately upon their submission, amazing us with his ability to do all of this on top of his other responsibilities. Steve was diagnosed with brain cancer in 2004 but insisted on editing chapters for the fifth edition right through the compiling of the chapters. The book was published in early 2007, not long before his death in May 2007.

On behalf of everyone who contributed to the sixth edition of *Fields Virology*, we dedicate this book to the memory of Stephen E. Straus, MD.

Carlos F. Arias, MD

Professor
Department of Developmental Genetics and
Molecular Physiology
Instituto de Biotecnología
Universidad Nacional Autónoma de México
Cuernavaca, Morelos, Mexico

Ann M. Arvin, MD, PhD

Professor and Head of Department
Department of Hepatology
Hospices Civils de Lyon
Lyon, France

In the early 1980s, Bernie Fields originated the idea of a virology reference textbook that combined the molecular aspects of viral replication with the medical features of viral infections. This broad view of virology reflected Bernie's own research, which applied molecular and genetic analyses to the study of viral pathogenesis, providing an important part of the foundation for the field of molecular pathogenesis. Bernie led the publication of the first three editions of *Virology* but unfortunately died soon after the third edition went into production. The third edition became *Fields Virology* in his memory, and it is fitting that the book continues to carry his name.

We are pleased that the printed book of the sixth edition of *Fields Virology* contains four-color art throughout and that an e-book version accompanies the printed book as well. We have increased the numbers of figures in each chapter, and with the color and availability of the figures from the e-book for use as slides, most chapters should have sufficient figures for slides for one lecture. There have been continued significant advances in virology since the previous edition 6 years ago, and all of the chapters have been updated to reflect these advances. Our increased knowledge of virology has caused us to use shortened lists of key references (up to 200 in most cases) in the printed book to save space, whereas complete reference lists appear as part of the e-book. We have retained the general organization of the earlier editions for the sixth edition of *Fields Virology*. Section I contains chapters on general aspects of virology, and Section II contains chapters on replication and medical aspects of specific virus families and specific viruses of medical importance. In Section I, we have added a new emphasis on virus discovery in the Diagnostic Virology chapter and emerging viruses in the Epidemiology chapter to address the interest in discovery of new viruses and emerging viruses. In Section II, we have added new chapters on circoviruses and mimiviruses and have added a new section on Chikungunya virus to the alphavirus chapter.

Numerous chapters have been updated to include the latest information on outbreaks during the past 5 years, including pandemic H1N1 influenza, new adenovirus serotypes, noroviruses, human polyomaviruses, the re-emergence of West Nile virus in North America, novel coronaviruses, novel Coxsackie and rhino viruses, and other emerging and re-emerging viruses. Important advances in antivirals, including new hepatitis C virus protease inhibitors and HIV integrase inhibitors, have been described. As with the previous edition, we have continued to combine the medical and replication chapters into a single chapter to eliminate duplication and to present a more coherent presentation of that specific virus or virus family. The main emphasis continues to be on viruses of medical importance and interest; however, other viruses are described in specific cases where more is known about their mechanisms of replication or pathogenesis. Although not formally viruses, prions are still included in this edition for historical reasons and because of the intense interest in the infectious spongiform encephalopathies.

We wish to thank Lisa Holik of Harvard Medical School, Richard Lampert of Lampert Consultancy, Grace Caputo of Dovetail Content Solutions, Chris Miller of Aptara, and Leanne Vandetty and Tom Gibbons and all of the editorial staff members of Lippincott Williams & Wilkins for all their important contributions to the preparation of this book.

Preface xv

VOLUME 1

SECTION I:

General Virology 1

- 1** Virology: From Contagium Fluidum to Virome 1
Lynn W. Enquist and Vincent R. Racaniello

- 2** Principles of Virology 21
Richard C. Condit

- 3** Principles of Virus Structure 52
Stephen C. Harrison

- 4** Virus Entry and Uncoating 87
Ari Helenius

- 5** Viral Replication Strategies 105
Sean Whelan

- 6** Virus Assembly 127
Eric Hunter

- 7** Viruses, Cell Transformation, and Cancer 153
Daniel DiMaio and Hung Fan

- 8** Innate Responses to Viral Infections 189
Akiko Iwasaki and Ruslan Medzhitov

- 9** Adaptive Immune Response to Viral Infections 214
Thomas J. Braciale, Young S. Hahn, and Dennis R. Burton

- 10** Pathogenesis of Viral Infection 254
Mark T. Heise and Herbert W. Virgin

- 11** Virus Evolution 286
Edward C. Holmes

- 12** Epidemiology 314
Neal Nathanson and William J. Moss

- 13** Antiviral Agents 338
Donald M. Coen and Douglas D. Richman

- 14** Immunization Against Viral Diseases 374
Barney S. Graham, James E. Crowe, Jr., and Julie E. Ledgerwood

- 15** Diagnostic Virology 414
Gregory A. Storch and David Wang

SECTION II:

Specific Virus Families 453

Picornaviridae

- 16** *Picornaviridae*: The Viruses and Their Replication 453
Vincent R. Racaniello

- 17** Enteroviruses: Polioviruses, Coxsackieviruses, Echoviruses, and Newer Enteroviruses 490
Mark A. Pallansch, M. Steven Oberste, and J. Lindsay Whitton

- 18** Rhinoviruses 531
James E. Gern and Ann C. Palmenberg

- 19** Hepatitis A Virus 550
F. Blaine Hollinger and Annette Martin

Calciviridae

- 20** *Calciviridae*: The Noroviruses 582
Kim Y. Green

Astroviridae

- 21** Astroviruses 609
Ernesto Méndez and Carlos F. Arias

Togaviridae

- 22** *Togaviridae* 629
Richard J. Kuhn

- 23** Alphaviruses 651
Diane E. Griffin

HISTORY

Arenaviruses cause chronic infections of rodents indigenous to Europe, Africa, the Americas, and perhaps other continents. These asymptotically infected animals move freely in their natural habitat and may invade human habitation; when humans come in contact with excreted viruses, disease may result. Arenavirus infections of humans are common and in some cases severe; several members of the group are responsible for severe acute infections termed *hemorrhagic fevers*. The mechanisms that have evolved to ensure chronic infection and intergenerational survival of the virus in rodents are complex and specific to the particular rodent–virus combination, and their elucidation over the past 60 years has led to a deeper understanding of immunology and immunopathology.¹⁶⁴

Lymphocytic choriomeningitis virus (LCMV) was the first isolated arenavirus, discovered in 1933 during the study of samples from a St. Louis encephalitis epidemic.¹⁸⁵ It was soon

found to be a cause of aseptic meningitis²⁰⁶ and to be identical to an agent that chronically infected mouse colonies.²²² This launched a series of studies that showed LCMV to be a common human pathogen and a fascinating virus with many lessons for biologists.^{31,32,164}

By the 1960s, several other viruses had been discovered and found to share common morphology,¹⁶⁰ serology,¹⁹² biochemical features, and a natural history that depended on chronic infection of rodent reservoirs, leading to the recognition of the *Arenaviridae* family, named after the sandy (Latin, *arenosus*) appearance of the ribosomes originally seen in thin sections of virions.¹⁹² Some of these viruses caused hemorrhagic fevers (Table 43.1), whereas others were apparently not pathogenic for or rarely infected humans (Table 43.2). Since the isolation of Tacaribe virus (TACV),⁵⁵ new arenaviruses have continued to be discovered in the Americas on the average of one every 3 years, including three lethal new viruses: Guanarito,¹⁹⁸ Sabia in 1990,¹³⁰ and Whitewater Arroyo in 1996.⁷⁹ As a result of new technologies of deep sequencing and genome discovery, several new arenaviruses have been revealed in the past decade in both the New World (NW) and Old World (OW) branches of the *Arenaviridae*.

CLASSIFICATION OF VIRUSES WITHIN FAMILY

The *Arenaviridae* consists of a unique genus (*Arenavirus*) containing 24 unique species currently recognized by the International Committee on Taxonomy of Viruses (ICTV), as well as several newly discovered viruses whose taxonomic status has not yet been determined by the ICTV (see Table 43.1). The original classification of arenaviruses, based mainly on virus antigenic properties, identified two groups: the NW (also referred to as Tacaribe serocomplex) and the OW (also referred to as Lassa-Lymphocytic choriomeningitis serocomplex) including viruses from Africa and the globally distributed prototypic arenavirus, LCMV. Results derived from molecular genetic studies are consistent with findings from comparative serology.

The OW group consists of a single lineage composed of five species (*Lassa virus*, *Mobala virus*, *Ippy virus*, *Mopeia virus*, and *Lymphocytic choriomeningitis virus*), and several newly discovered viruses including Kodoko, Morogoro, Dandenong and Lujo,^{39,119,166} whereas the NW group is composed of four lineages: clades A, B, C, and A/Rec (Fig. 43.1). Clade A contains five species (*Flexal virus*, *Parana virus*, *Pichinde virus*, *Pirital virus*, and *Allpahuayo virus*), whose internal genetic relationships are not well established.³⁹ Clade B contains eight species

TABLE 43.1 Arenaviruses That Are Known to Be Human Pathogens

Virus	Host in nature	Geographic distribution	Disease	Clinical picture	Case fatality
Lymphocytic choriomeningitis	<i>Mus domesticus</i> ; <i>Mus musculus</i>	Europe, Americas, perhaps elsewhere	Lymphocytic choriomeningitis	Usually recognized as aseptic meningitis; more severe central nervous system disease occasionally occurs. Most common clinical form, rarely diagnosed, is probably febrile illness without neurologic involvement. May cause transient hydrocephalus during acute infection or congenital hydrocephalus and chorioretinitis after fetal infection	<1%
Lassa	<i>Mastomys</i> spp.	West Africa	Lassa fever	Severe systemic illness with changes in vascular permeability and vasoregulation. Worst cases often associated with bleeding	15%
Junin	<i>Calomys musculus</i>	Argentina Pampas	AHF	Classical viral hemorrhagic fever. Similar to Lassa, except thrombocytopenia, florid bleeding, and neurologic manifestations much more common	15%–30%
Machupo	<i>Calomys callosus</i>	Beni region of Bolivia	Bolivian hemorrhagic fever	As in AHF	25%
Guanarito	<i>Sigmodon alstoni</i> ; <i>Zygodontomys brevicauda</i>	Venezuela	Venezuelan hemorrhagic fever	Probably similar to AHF	25%
Sabia	Unknown	Brazil	Not yet named	Probably similar to AHF. Extensive hepatic necrosis seen in one of the two cases not treated with ribavirin	1/3
Whitewater Arroyo	<i>Neotoma albigula</i>	New Mexico, California, United States	Not yet named	Hemorrhagic fever with liver failure	3/3

AHF, Argentine hemorrhagic fever.

(*Sabia virus*, *Cupixi virus*, *Guanarito virus*, *Amapari virus*, *Junin virus*, *Machupo virus*, *Tacaribe virus*, and *Chapare virus*), which form three well-supported lineages. Clade C is composed of only two established species, *Oliveros virus* and *Latino virus*, and a potential third member, Pinhal virus, for which little information is available. Clade A/Rec comprises all North American arenaviruses: *Whitewater Arroyo virus*, *Tamiami virus*, *Bear Canyon virus*, and the newly discovered Skinner Tank and Catarina viruses. As with clade A, intraclade A/Rec relationships are poorly resolved, owing to limited sequencing data and the incongruence of phylogenetic data derived from different genes. The geographic distribution of each arenavirus is determined by the range of its natural specific rodent res-

ervoir, with the exception of TACV, which was isolated from fruit-eating bats.^{59,84}

Recently, high-throughput sequencing and metagenomic pathogen discovery approaches have led to the identification and isolation of two highly divergent arenaviruses from cases of inclusion body disease, a common infectious disease of captive snakes.²¹⁵ These viruses show typical ambisense arenavirus genome organization but have a GP2 reminiscent of filoviruses. These findings indicate that arenavirus natural hosts are broader than previously thought and not restricted to mammals. In addition, significant genetic divergence between these newly identified reptile arenaviruses and known mammalian arenaviruses together with biological differences between rep-

TABLE 43.2 Arenaviruses Not Known to Be Significant Human Pathogens

Virus	Host in nature	Geographic distribution	Comments	Year isolated
Tacaribe	Unknown	Trinidad	Originally isolated from <i>Artibeus</i> bats in 1956–58 and not found in subsequent attempts; bats may be reservoir	1956
Amapari	<i>Oryzomys goeldi</i> , <i>Neacomys guianae</i>	Brazil	Apparently has two rodent reservoirs	1964
Parana	<i>Oryzomys buccinatus</i> ?	Paraguay	Reservoir not well established	1965
Tamiami	<i>Sigmodon hispidus</i>	United States	Antibodies detected in a few humans without disease	1963, 1965
Pichinde	<i>Oryzomys albigularis</i>	Colombia	Several asymptomatic laboratory infections	1967
Latino	<i>Calomys callosus</i>	Bolivia	Thought to be nonpathogenic for humans	1965
Flexal	<i>Oryzomys</i> spp.?	Brazil	Two laboratory infections with disease	1975
Oliveros	<i>Bolomys obscurus</i>	Argentina	Found during field studies of Junin virus; still under evaluation	1989
Ippy	<i>Arvicanthis</i> spp.	Central African Republic	Found to be an arenavirus in 1985; see Mopeia	1970
Mopeia	<i>Mastomys natalensis</i>	Mozambique, Zimbabwe	One of several non-Lassa arenaviruses from <i>Mastomys</i> spp. in Africa	?
Mobala	<i>Praomys</i>	Central African Republic	See Mopeia	?

tiles and mammals have raised new questions about the biology and evolution of arenaviruses.

The originally established species demarcation criteria included (a) association with a specific host species or group of species, (b) geographic niche, (c) association with human disease, (d) differences in antigenic cross-reactivity, and (e) sig-

nificant sequence difference from other species in the genus. However, often limited information and difficulties associated with its analysis regarding these criteria have led more recently to emphasize mainly genetic criteria to define *Arenavirus* species. This approach, however, faces the problem of how to correctly assign a cutoff value for species demarcation owing to

FIGURE 43.1. Location of American arenaviruses with their natural host. (Courtesy of Dr. S. Nichol, Centers for Disease Control and Prevention.)

biased sequence availability. There are many fewer OW than NW arenavirus sequences; however, OW sequences include most complete intraspecies sequences. Therefore, intraspecies diversity is likely underestimated among NW arenaviruses, whereas the interspecies diversity could be underestimated for OW arenaviruses. Notably, sequence comparison of the same genome region for a large number of isolates revealed similar degree of diversity in an OW arenavirus (Lassa virus [LASV]) and two NW arenaviruses (Whitewater Arroyo virus [WWAV] and Pirital virus [PIRV]).³⁹ These findings suggest that accurate classification of a new arenavirus isolate may require to follow the *Arenavirus* species definition together with comparing the sequence of the new isolate with the larger available set of sequences.

Virion Structure

Arenavirus virions are pleomorphic when examined by cryo-electron microscopy, ranging in size from 40 to more than 200 nm in diameter^{39,103} (Fig. 43.2). Virions contain a surface envelope that is studded with evenly spaced spikes that correspond

FIGURE 43.2. Electron microscopy of arenaviruses. **A:** Thin section showing lymphocytic choriomeningitis virus budding from infected BHK-21 cells. Typical 110-nm particles contain numerous electron-dense 20-nm ribosomes that were the basis for the family name. **B:** Cryo-electron microscopy of unstained, purified virions at $-4\ \mu\text{m}$ defocus to illustrate surface topography. Refined images of arenavirus glycoprotein spikes, Z protein, and ribonucleoprotein densities were obtained by single-particle image analysis of Pichinde glycoprotein complexes from particle edges (inset, **left**). Nucleoprotein packing is evident in refined images of ribonucleoprotein from virion centers (inset, **right**). Bar indicates 10 nm. (Courtesy of B. W. Neuman, J. W. Burns, R. Milligan, and M. J. Buchmeier.)

to glycoprotein (GP) projections consisting of complexes of the viral GPs—GP1 and GP2. The surface GPs are aligned with subjacent Z protein and ribonucleoprotein (RNP) densities, which are packed into a two-dimensional lattice at the inner surface of the viral membrane.^{103,161} Virions contain the L and S genomic RNAs as helical nucleocapsid (NC) structures that are organized into circular configurations, with lengths ranging from 400 to 1,300 nm.²⁴⁰ The L and S genomic RNA species are not present in equimolar amounts within virions (L:S ratios $\sim 1:2$), and low levels of both L and S antigenomic RNA species are also present within virions. In addition, it has been documented that host ribosomes can be incorporated into virions, although the biological significance of this remains to be determined.^{28,159}

Genome Structure and Organization

Arenaviruses are enveloped viruses with a bisegmented negative-sense single-stranded RNA genome and a life cycle restricted to the cell cytoplasm. Individual arenaviruses exhibit some variability in the lengths of the two genomic RNA segment, L (ca 7.2 kb) and S (ca 3.5 kb); however, their overall organization is well conserved across the virus family.³⁰ Arenavirus coding strategy has unique features compared to other NS RNA viruses. Each arenavirus genome segment uses an ambisense coding strategy to direct the synthesis of two polypeptides in opposite orientation, separated by a noncoding intergenic region (IGR) with a predicted folding of a stable hairpin structure (Fig. 43.3). The S RNA encodes the viral glycoprotein precursor (GPC; ca 75 kDa) and the nucleoprotein (NP; ca 63 kDa),

LCMV Genome Organization

FIGURE 43.3. Schematic diagram showing coding strategy for the L and S RNAs of the arenaviruses. Stem-loop structures indicate noncoding regions of each genomic segment. The lower portion of the diagram summarizes the transcription and replication events for the S genomic segment. As a consequence of this arrangement, the GPC and Z open reading frames can be transcribed only after initiation of replication of viral genomic RNA.

whereas the L RNA encodes the viral RNA-dependent RNA polymerase (RdRp, or L polymerase) (ca 200 kDa) and a small (ca 11 kDa) RING finger protein (Z) that functions as a matrix protein.³⁰ This situation—where in one region the S and L RNA are negative sense and in a second, nonoverlapping region they are pseudo-positive sense—led investigators to coin the term *ambisense* to describe the arenavirus coding strategy. The qualifier *pseudo* is used because there is no evidence that the genomic S and L RNAs can function as messenger RNAs (mRNAs) and be directly translated into GPC and Z proteins, respectively.

Arenaviruses exhibit high degree of sequence conservation at the 3' end of the L and S RNA segments (17 out of 19 nucleotides [nt] are identical), suggesting that this conserved terminal sequence element constitutes the virus promoter for polymerase entry.^{30,151} Arenavirus genomes and antigenomes exhibit a high degree of complementarity between their 5' and 3' termini, and the 5' and 3' ends of both L and S genome segments are predicted to form panhandle structures.^{30,151,215} This prediction is supported by electron microscopy data showing the existence of circular RNP complexes within arenavirus virion particles.²⁴⁰ This terminal complementarity may reflect the presence at the 5' ends of *cis*-acting signals sequences that provide a nucleation site for RNA encapsidation, which is required to generate the NC templates recognized by the virus polymerase. Terminal complementarity may be also a consequence of strong similarities between the genome and antigenome promoters used by the virus polymerases. This terminal complementarity has been proposed to favor the formation of both intra- and intermolecular L and S duplexes that might be part of the replication initiation complex; however, its mechanistic aspects remain undefined.¹⁹⁹ For several arenaviruses, an additional nontemplated G residue has been detected on the 5' end of their genome RNAs.⁸²

Arenavirus IGRs are predicted to fold into a stable hairpin structure. Transcription termination of the S-derived NP and GP occurs at multiple sites within the predicted stem of the IGR, suggesting that a structural motif rather than a sequence-specific signal promotes the release of the arenavirus polymerase from the template RNA.^{30,151} There are significant differences in sequence and predicted folded structure between the S and L IGR; however, among isolates and strains of the same *Arenavirus* species, the S and L IGR sequences are highly conserved. Some arenaviruses, including LCMV, LASV, and Pichinde virus (PICV), contain a single predicted stem loop within the S IGR, whereas the S IGR of others, such as TACV and Mopeia virus (MOPV), are predicted to contain two distinct stem loops.^{151,151,214}

ARENAVIRUS LIFE CYCLE

Cell Attachment and Entry

Consistent with a broad host range and cell-type tropism, a highly conserved and widely expressed cell surface receptor for extracellular matrix (ECM) proteins—alpha-dystroglycan (α -DG)—has been identified as a main receptor for LCMV, LASV, and several other arenaviruses.^{35,115,151} Posttranslational modifications of α -DG, including O-mannosylation and LARGE-dependent glycosylation, are critical for α -DG's function as both an ECM and OW and clade C NW arenavirus receptor.^{151,190} These findings indicate that similar α -DG-derived glycan structures are recognized by both ECM proteins

and surface arenavirus GPs. Intriguingly, recent genome-wide studies have uncovered evidence of positive selection of specific LARGE alleles within the Yoruba people in West Africa where LASV is endemic.¹⁹⁵ However, many other arenaviruses appear to use an alternative receptor and human transferrin receptor 1 (TfR1) was identified as a cellular receptor used for cell entry of NW hemorrhagic fever arenaviruses Junin virus (JUNV) and Machupo virus (MACV).¹⁸⁴

Upon receptor binding, arenavirus virions are internalized by smooth-walled vesicles into a low-pH subcellular environment that triggers a pH-dependent membrane fusion step between cell and viral membranes that is mediated by GP2 and results in the release of the virus RNP into the cytoplasm of the cell where viral RNA synthesis, both transcription of replication, take place. Consistent with the use of TfR1 as a primary receptor for cell entry, JUNV was found to follow a clathrin-mediated endocytosis as its main route of entry.¹³⁸ Nevertheless, although TfR1 is internalized and recycles through early endosomes (pH ~6), optimal fusion activity of JUNV GP requires a significantly lower (<5.5) pH, suggesting that JUNV may redirect TfR1 from its normal recycling pathway into the late endosomes, a process likely influenced by the multivalent nature of the virus particle. In contrast, cell entry of the OW arenaviruses LCMV and LASV appears to use a rather unique endocytic pathway independent of clathrin, caveolin, dynamin, and actin.^{187,188,191,208,227} (Fig. 43.4). Consistent with these findings, endosomal trafficking of LASV and LCMV was only minimally affected by dominant negative forms of Rab5 and Rab7, which are small guanine triphosphatases (GTPases) involved in vesicular trafficking into early and late, respectively, endosomes. Moreover, LCMV was found to circumvent Rab5/EEA-1 early endosomes. LCMV and LASV GP have a high binding affinity for α -DG and thereby the unusual endocytic pathway followed by these viruses may reflect the natural cellular trafficking of α -DG. Nevertheless, it cannot be ruled out that binding of GP to α -DG could trigger a novel route of entry for dystroglycan that is tailored specifically to benefit virus cell entry as previously documented for other pathogens.

Expression and Replication of the Viral Genome

The fusion between viral and cellular membranes releases the viral RNP into the cytoplasm, which is ensued by the onset of viral RNA synthesis. Transcription termination of subgenomic nonpolyadenylated viral mRNAs were mapped to multiple sites within the distal side of the IGR, which suggested that the IGR acts as a bona fide transcription termination signal for the virus polymerase.

The NP and L coding regions are transcribed into a genomic complementary mRNA, whereas the GPC and Z coding regions are not translated directly from genomic RNA, but rather from genomic sense mRNAs that are transcribed using as templates the corresponding antigenome RNA species, which also function as replicative intermediates (Fig. 43.5). LCMV mRNAs have four to five nontemplated nucleotides and a cap structure at their 5' ends, which are likely obtained from cellular mRNAs via cap-snatching mechanisms whose details remain to be determined. A recently described endonuclease activity associated with the arenavirus L polymerase could play a critical role in this process.¹⁵⁷

The NP—the most abundant viral polypeptide both in infected cells and virions—is the main structural element of

The diagram illustrates the replication cycle of the influenza A virus. At the top, the **Genome** is shown as a set of eight RNA segments, including **GP** (Glycoprotein) and **NP** (Nucleoprotein). A viral polymerase complex, labeled **L**, is associated with the 3' end of the genome. An arrow labeled **Replication** points to the **Antigenome** below. The **Antigenome** is a full-length, double-stranded copy of the viral genome. From the **Antigenome**, **Transcription** produces **NP mRNA** (3' to 5'), which is then **Translated** into **NP** proteins. Simultaneously, **Transcription** of the **Antigenome** produces **GP mRNA** (5' to 3'), which is **Translated** into **GP** proteins. The **NP** and **GP** proteins are shown assembling into new viral particles.

the viral RNP and plays an essential role in viral RNA synthesis. Recent evidence indicates that NP exhibits interferon type I (IFN-I) counteracting activity that was mapped to the C-terminus of NP.^{140,141,143} Two recently determined crystal structures of LASV NP at 1.80¹⁸³ and 1.5⁹⁰ Å resolution identified distinct N- and C-terminal domains connected by a flexible linker. The N-terminal domain was proposed to contain a potential cap-binding site that could provide the host-derived primers to initiate transcription by the virus polymerase.¹⁸³

The C-terminal domain has a folding that mimics that of the DEDDH family of 3'-5' exoribonucleases like the one associated with severe acute respiratory syndrome (SARS) coronavirus nsp14 protein.¹⁵⁵ Functional studies confirmed the 3'-5' exoribonuclease activity of LASV NP, which was proposed to

The diagram illustrates the replication cycle of the feline coronavirus. It shows a cell being infected by the virus. The viral genome (MG RNA) is transcribed into CAT mRNA, which then exhibits CAT activity. The genome is also replicated. The replication process involves the synthesis of NP, L, and Z proteins. These proteins, along with GP, assemble into VLPs (Virus-Like Particles). The VLPs then undergo budding to form new virus particles.

FIGURE 43.5. Scheme of the lymphocytic choriomeningitis virus (LCMV) minigenome (MG) rescue system. This system allows us to re-create the steps of the virus life cycle intracellularly. LCMV RNA analogs, or MG with correct termini, are synthesized intracellularly using either a T7 RNA polymerase or an RNA pol-I expression system. Co-transfection with plasmids expressing the viral *trans*-acting factors L and nucleoprotein (NP) allow for the generation of viral ribonucleoprotein (MG RNA encapsidated by NP) that is substrate for the plasmid-supplied virus L polymerase. The virus polymerase directs the synthesis of two RNA species: the MG RNA (replicative species) and a subgenomic messenger RNA that directs expression of the reporter gene of choice, *CAT*, in this case. Incorporation of plasmids expressing Z and glycoprotein results in assembly and budding of infectious LCMV virus-like particles.

be critical for the anti-interferon (IFN) activity of NP but dispensable for the role of NP on replication and transcription of the viral genome.⁹⁰ This assertion, however, is difficult to reconcile with the finding that TACV NP, despite containing the conserved DEDDH residues at the active site of the exoribonuclease domain, has a dramatically reduced anti-IFN activity,¹⁴² and the finding that an LCMV with a mutant NP lacking the 3'-5' exoribonuclease had a large decrease in fitness during its replication in IFN-deficient Vero cells.¹⁴⁰

The arenavirus L protein has the characteristic sequence motifs conserved among the RdRp (L proteins) of NS RNA viruses.¹⁸¹ Detailed sequence analysis and secondary structure predictions done with the LASV L polymerase identified several regions of strong alpha-helical content and a putative coiled-coil domain at the N-terminus.²²⁸ Subsequent bioinformatic analysis together with biochemical and minigenome (MG)-based functional studies have shown that LASV L protein is likely organized into three distinct structural domains, and that at specific amino acid positions, LASV L can be split into N- and C-terminal parts that are able to functionally *trans*-complement each other.²⁷ Notably, the recent electron microscopy characterization of a functional MACV L protein has revealed a core ring domain decorated by appendages, which may reflect a modular organization of the arenavirus polymerase.¹¹⁴

Assembly and Budding

Assembly and cell release of infectious arenavirus progeny requires both Z and GPC, as well as the correct processing by the cellular site 1 protease (S1P) of GPC into GP1 (40–46 kDa) and GP-2 (35 kDa)^{116,125,178} Oligomers of GP1 and GP2 form the spikes that decorate the virus surface. GP1 located at the top of the spike and held in place by ionic interactions with the N-terminus of the transmembrane GP-2, mediates virus interaction with host cell surface receptors, whereas GP2 exhibits similarities with fusion active domains of other viral envelope proteins.^{66,80,236} GPC contains a 58-amino-acid signal peptide (SSP) that is expressed as a stable polypeptide in infected cells and it remains associated to the GP complex (GPCx). This SSP has been implicated in different aspects of the trafficking and function of the viral envelope GPs including the GP-2-mediated pH-dependent fusion process.^{2,203,237–239}

For most enveloped viruses, a matrix (M) protein is involved in organizing the virion components prior to assembly. Interestingly, arenaviruses do not have an obvious counterpart of M. The arenavirus RING finger protein Z is a structural component of the virion that has no homologue among other known NS RNA viruses. In LCMV-infected cells Z has been shown to interact with several cellular proteins including the promyelocytic leukemia (PML) protein and the eukaryote translation initiation factor 4E (eIF4E), which have been proposed to contribute to the noncytolytic nature of LCMV infection and repression of cap-dependent translation, respectively.^{54,229} Z has been shown to be the main driving force of arenavirus budding,^{169,218} a process mediated by the Z late (L) domain motifs: PTAP and PPPY similar to those known to control budding of several other viruses including HIV and Ebola virus, via interaction with specific host cell proteins.⁷⁸ Consistent with this observation Z exhibited features characteristic of bona fide budding proteins: 1) ability to bud from cells by itself, and 2) substituted

efficiently for other L domain. Targeting of Z to the plasma membrane, the location of arenavirus budding, strictly required its myristoylation.^{171,219} Results derived from cryo-electron microscopy of arenavirus particles¹⁶¹ were also consistent with the role of Z as a functional M protein.

ARENAVIRUS REVERSE GENETICS: IMPLICATIONS FOR THE INVESTIGATION OF ARENAVIRUS MOLECULAR AND CELL BIOLOGY

The generation of an infectious progeny of NS RNA viruses from cloned cDNA, referred to as reverse genetics, has revolutionized the analysis of cis-acting sequences and trans-acting proteins required for virus replication, transcription, maturation and budding. In addition, the possibility to generate predetermined specific mutations within the virus genome and analyze their phenotypic expression in the context of the virus natural infection provides investigator with novel and powerful approaches to investigate cellular and molecular mechanisms underlying virus-host interactions and their implications in viral pathogenesis. In addition, these developments have also paved the way for engineering recombinant viruses for vaccine and gene therapy purposes.

In contrast to positive-strand RNA viruses, deproteinized genomic and antigenomic RNAs of NS RNA viruses cannot function as mRNAs and are not infectious. Generation of biologically active synthetic NS viruses from cDNA requires *trans* complementation by all viral proteins involved in virus replication and transcription, and polymerases of NS RNA viruses recognize as templates an NC consisting of the genomic RNA tightly encapsidated by the NP, which associated with the virus polymerase proteins forms an RNP complex. These considerations hindered the application of recombinant DNA technology to the genetic analysis of these viruses. However, significant progress has been made in this area and for all NS RNA viruses, short model genomes (aka minigenomes (MG)) could be encapsidated and expressed by plasmid-encoded proteins. Moreover, it has become possible to rescue infectious virus entirely from cloned cDNAs for members of all families of NS RNA viruses.^{108,162}

Arenavirus Minigenome Systems

The first arenavirus MG rescue system was developed for LCMV.¹²² Subsequently MG systems were developed for LASV⁸⁷ and the NW arenaviruses PICV,¹¹⁷ TACV,¹³¹ and JUNV.³ Results derived from MG-based assays identified NP and L as the minimal viral trans-acting factors required for efficient RNA synthesis mediated by the virus polymerase. For LCMV both genetic and biochemical evidence indicated that oligomerization of L is required for the activity of the arenavirus polymerase.²⁰¹ Consistent with this finding, biochemical and MG-based functional studies have shown that LASV L protein contains both N- and C-termini sites that mediate L–L interaction. The use of MG-based assays facilitated mutation-function studies involving conserved acidic and basic amino acid residues within the N- and C-termini of LASV L protein uncovered several residues within the N-terminus of L that played a critical role in synthesis of viral mRNA but not in

RNA replication.^{88,124,201} The recent publication of a 2.13 Å resolution crystal structure and functional characterization of the N-terminal 196 residues (NL1) of the LCMV L protein uncovered an endonuclease functional domain similar to the one found in the N-terminus of the influenza virus PA protein.¹⁵⁷ MG-based assays have shown the endonuclease activity of NL1 to be critical for arenavirus transcription.

Mutation-function analysis of the genome 5′- and 3′-termini using the LCMV and LASV MG-based assays indicated that the activity of the arenavirus genomic promoter requires both sequence specificity within the highly conserved 3′-terminal 19 nt of arenavirus genomes and the integrity of the predicted panhandle structure formed via sequence complementarity between the 5′- and 3′-termini of viral genome RNAs.^{89,157,170} These studies revealed that arenavirus RNA replication and transcription are regulated in a coordinated manner. Likewise, MG-based assays provided direct experimental confirmation that the IGR is a bona fide transcription termination signal,¹⁷⁷ and that intracellular levels of NP do not determine the balance between virus RNA replication and transcription^{68,178,179}—a finding conceptually similar to that reported for the paramyxovirus respiratory syncytial virus.⁶⁸

Z was not required for intracellular transcription and replication of a LCMV MG; rather, Z exhibited a dose-dependent inhibitory effect on both transcription and replication of

LCMV MG.^{43–45,68} This inhibitory effect of Z has been also reported for TACV¹³¹ and LASV.^{87,131}

Generation of Recombinant Arenaviruses

Generation of infectious arenaviruses from cloned complementary DNAs (cDNAs) has been reported for LCMV,^{73,151,202} PICV,¹¹⁷ and JUNV.^{3,62,117} Both T7 RNA polymerase (RP)- and pol-I RP-based systems^{73,202} have been documented to launch intracellular synthesis of S and L genome, or antigenome, RNA species that were subsequently replicated and transcribed by the virus polymerase complex reconstituted intracellularly via plasmid-supplied L and NP (Fig. 43.6). Notably, rescue of PICV and JUNV using a T7RP-based system was efficiently achieved without requiring plasmid-supplied viral NP and L proteins,^{3,73,117} indicating that T7RP-mediated RNA synthesis produced viral antigenome RNA species that were substrate for encapsidation and replication as well as mRNAs that serve as a template to produce levels of NP and L sufficiently high to facilitate virus rescue. This finding parallels those reported for several other negative sense RNA viruses, including bunyaviruses,^{20,132} filoviruses,⁸⁵ and bornaviruses.²⁰⁵

The ability to generate recombinant arenaviruses with predetermined specific mutations and analyze their phenotypic expression in the context of the natural course of infection has opened new opportunities to investigate arenavirus–host

FIGURE 43.6. Brain of a BALB/c mouse inoculated intracranially with lymphocytic choriomeningitis virus (LCMV) Armstrong strain, 6 days previously. Abundant viral expression is seen in the choroid plexus (A) and in ependymal cells lining the third ventricle (B) when stained by monoclonal antibody 2-11.10 that detects glycoprotein 1 followed by fluorescein-labeled sheep antimouse immunoglobulin G. Mononuclear cell infiltration is prominent in the choroid plexus (C) and the meninges (D).

interactions that influence a variable infection outcome, ranging from virus control and clearance by the host defenses to long-term chronic infection associated with subclinical disease, and severe acute disease including hemorrhagic fever. Thus, studies with recombinant lymphocytic choriomeningitis virus (rLCMV)/vesicular stomatitis virus glycoprotein (VSVG) uncovered the arenavirus GP as a viral Achilles' heel and provided the foundations for a novel strategy to develop safe and effective live attenuated arenavirus vaccines.^{178,179} Likewise, the use of rLCMV/VSVG facilitated studies aimed at understanding the regulation of CD8⁺ T-cell function within the infected brain,¹⁸⁰ and how viruses can induce organ-specific immune disease in the absence of molecular mimicry and without disruption of self-tolerance.¹⁴⁹ Other rLCMVs have been used to investigate pathways of LASV cell entry¹⁸⁷ and the role of NP in the inhibition of induction of IFN-I by LCMV.¹⁴⁰ Likewise, the use of recombinant arenaviruses where a canonical furin cleavage site substituted for the S1P cleavage site within GPC illustrated the critical role played by the S1P-mediated processing of arenavirus GPC in the virus life cycle.^{3,189,224} The rescue of attenuated and virulent forms of PICV^{117,128} or the docile and aggressive strains of LCMV^{41,60,61} have allowed for the identification of specific genetic determinants of virus virulence. However, despite these successes, the ability to rescue recombinant arenaviruses expressing additional genes of interest posed unexpected difficulties. Approaches successfully employed with other NS RNA viruses including the use of an internal ribosome entry site (IRES), or of the picornavirus self-cleaving 2A sequence, did not work when applied to LCMV.⁶¹ This problem was finally overcome by the generation of trisegmented rLCMV (r3LCMV) containing one L and two S segments. For this, each of the two S segments was altered to replace one of the two viral open reading frames (ORFs), GPC or NP, by a gene of interest (GOI).⁶¹ The rationale for this approach was that the physical separation of GP and NP into two different S segments would represent a strong selective pressure to select and maintain a virus capable of packaging 1L and 2S segments (Fig. 43.7). Various r3LCMV have been rescued that express one or two additional GOI. Depending on the GOI expressed, with gene size and function being critical parameters, these r3LCMV have shown little or no attenuation

FIGURE 43.7. Accumulation of Machupo virus (arrow) budding from acinar cells of the salivary gland of a virus-infected large vesper mouse (*Calomys callosus*). Abundant virions in the lumen readily contaminate saliva (22,000 \times). (Courtesy of F. A. Murphy.)

and long-term genetic stability in cultured cell. In contrast, the use of r3LCMV to study virus–host interactions in mice has encountered some limitations owing to the observation that even r3LCMV with wild-type growth properties in cultured cells exhibited an attenuated phenotype in the mouse owing to reasons that remain to be determined.

PREVENTION AND CONTROL

Lymphocytic Choriomeningitis Virus Infection

LCMV infections in humans are rarely fatal. Two fatalities resulting from overwhelming systemic disease resembled hemorrhagic fever cases. A single well-studied encephalitis case showed mononuclear cell infiltrates in the meninges and around vessels and glial nodules in the deeper structures.²³² Fluorescent antibodies detected viral antigen in meninges and in cortical neurons.

The gross and light microscopic lesions found postmortem in arenaviral hemorrhagic fever patients rarely account for their demise.²³¹ Petechial hemorrhages of the skin and internal organs, cutaneous ecchymoses, and evidence of mucosal bleeding are common. Serous effusions, interstitial pneumonitis and pulmonary edema, and evidence of secondary bacterial infection are sometimes seen. Microscopic evidence of disseminated intravascular coagulation or vasculitis is uncommonly found and is not a regular feature of these diseases. Adequate studies of vascular endothelium are not available.

Focal necrosis may be present in several organs, including the liver, kidney, and adrenal cortex; fluorescent antigen tracings or virus titrations generally correspond to these lesions,^{135,230} as they do in experimental animal studies.⁴² These lesions usually contain a few mononuclear phagocytes as the only inflammatory cell contribution. Lymphoid depletion or necrosis in the marginal zone of the splenic periarteriolar lymphoid sheath is also present.²³⁰ Secondary changes associated with shock are usually found and may be responsible for the frequent presence of some degree of myocardial damage or myocarditis; however, virus has not been detected in the limited cardiac tissue studied.

Hemorrhages are common in the South American hemorrhagic fevers, in keeping with the low platelet counts. Thrombocytopenia is probably caused, at least in part, by maturation arrest of the megakaryocytes attributable to the high levels of IFN present in these patients.¹²⁶ In Lassa fever, thrombocytopenia is less marked, and liver involvement is more extensive. Although death does not appear to be caused by hepatic failure, the liver is an important site of virus replication, and the levels of aspartate transaminase (AST) in serum are proportional to the risk of dying.^{146,147}

Arenavirus diseases begin with a gradual onset of fever and myalgia, followed by systemic and hematopoietic cell abnormalities. In the viral hemorrhagic fevers (VHFs), a period of viremia lasting 1 to 3 weeks is accompanied by intense systemic symptoms; the occurrence of an effective immune response is concordant with clinical recovery and cessation of viremia. In LCMV infection, rare fatal cases have occurred with a pattern resembling that of VHF,²¹¹ although usually LCMV infection results in a febrile disease with accompanying viremia, often followed by central nervous system (CNS) disease. During the CNS disease, there is no viremia; however, virus is still detectable

FIGURE 43.8. Probable pathogenesis of human lymphocytic choriomeningitis (LCM). In the **bottom panel**, results of inoculation of a normal human volunteer with lymphocytic choriomeningitis virus (LCMV) are shown. These and other human data show an initial period of 1 to 2 weeks' viremia associated with fever, leukopenia, and systemic symptoms. This is followed by the onset of the cellular immune response with meningeal inflammation leading to mild transient central nervous system (CNS) disease. Virus was isolated from the cerebrospinal fluid. In the **top panel**, the course of infection in a patient with Hodgkin disease, immunosuppressed by disease and chemotherapy, is shown. LCMV was inoculated in hopes of favorably influencing the underlying disease. Viremia continued as long as measured; no immunofluorescence assay, complementation fixation, or neutralizing antibodies developed; and there was no overt CNS disease. At the time of death, possibly secondary to bacterial pneumonia, there were high titers of virus present in brain (B), spleen (S), and tumor tissue (T). WBC, white blood cell. (Adapted from Genovesi EV, Johnson AJ, Peters CJ. Susceptibility and resistance of inbred strains of Syrian golden hamsters [*Mesocricetus auratus*] to wasting disease caused by lymphocytic choriomeningitis virus: pathogenesis of lethal and non-lethal infections. *J Gen Virol* 1988;69[Pt 9]:2209–2220.)

in cerebrospinal fluid (CSF), and the pathogenesis is believed to be immunopathologic.

Although LCMV is usually believed to be as a viral meningitis, deeper neurologic involvement is observed in a minority of cases, perhaps 10% or fewer in naturally observed outbreaks that provide some possibility of case ascertainment.^{52,95,225} If a febrile prodrome is present, meningeal signs usually begin about 10 days later, often after a brief hiatus in symptoms and fever (Fig. 43.8). Encephalitis has been diagnosed in 5% to 34% of hospitalized patients with documented LCMV.^{1,69,152} Full recovery is usual, although occasional deaths do occur.

The clinical laboratory abnormalities at the time of CNS involvement are usually confined to the CSF, which shows an increase in cells into the hundreds or low thousands, predominantly mononuclear in type. Protein is usually modestly elevated (50–150 mg%), and sugar may be low in

one-fourth of the patients, sometimes reaching values below 20 mg/dL.¹⁹

Rare neurologic presentations attributed to LCMV include ascending myelitis, transverse myelitis, and bulbar paralysis.¹ The course of acute LCMV has also been complicated by hydrocephalus. One case was believed to have posterior fossa arachnoiditis and was treated with ventriculomastoidostomy.²²⁰ Another was transient,⁹⁵ and a third required the placement of a ventricular reservoir.¹¹⁸ The latter case had evidence (by computed tomography) of periventricular edema and lateral ventricular enlargement, suggesting that the major lesion was ependymal inflammation. Both ependymal and meningeal inflammation are prominent lesions in experimental infections and in fatal LCMV encephalitis.²³² Nerve deafness has been associated with LCMV infection in two cases.⁹⁴ The occurrence of eighth nerve involvement in another OW arenavirus

disease (Lassa fever) suggests that these observations may represent a true causal relationship.

A surprising and illuminating recent finding has been the discovery of fatal LCMV infection in transplant patients.^{6,70,166,172} Two donors died of CNS hemorrhage and infected eight solid organ recipients; all recipients died, except one who received intravenous ribavirin and decreased immunosuppression. The cases were remarkably similar to three earlier fatal cases inoculated with LCMV in an attempt to cause regression in their lymphomas refractory to chemotherapy.⁹⁶ The clinical syndrome consisted of a systemic illness with thrombocytopenia, elevated transaminases, coagulation disorders, and involvement of lung, liver, and kidney. CNS abnormalities were seen but overshadowed by the severe systemic illness that resembled Lassa fever. The illness resembled the rare cases of VHF-like disease described previously²¹¹ and the milder illnesses observed in a carefully studied hospital outbreak.^{223,225} Presumably, the lack of an effective T-cell response allowed rampant virus replication and also prevented the development of the typical immunopathologic meningitis.

Lassa Fever

Infection with LASV leads to the gradual onset of fever and malaise after an incubation period of about 10 days (range, 5–21 days). As the process develops, there is an increase in fever and myalgia, with severe prostration. Gastrointestinal manifestations such as abdominal pain, nausea and vomiting, diarrhea, or constipation are common. Sore throat occurs in two-thirds of cases and is usually accompanied by objective inflammatory or exudative pharyngitis. Retrosternal pain and cough are frequent, and pleural effusions may develop. Bleeding manifestations are seen in fewer than one-third of patients but signal an unfavorable prognosis. Signs of increased vascular permeability such as facial edema or pleural effusions are present in a minority of patients and also suggest a poor prognosis. Mortality in hospitality patients is 15% to 20%.^{15,75–77,144,223}

A careful case-control study comparing Lassa fever to other febrile diseases seen in a West African hospital found several features significantly associated with Lassa fever, including bleeding, edema, exudative pharyngitis, conjunctivitis, and pharyngitis; however, the positive predictive values were only 0.61 to 0.74.²²³ The same study also found vomiting, sore throat, tachypnea, or bleeding to predict a 2.5-fold or higher increased risk of death. Despite the relative nonspecificity of the clinical findings, more than three-fourths of patients believed to have severe Lassa fever are confirmed virologically. Lassa fever is a major pediatric problem as well.^{150,156} Disease is more difficult to diagnose clinically. Occasional cases of infants developing anasarca have been described.

The course of fatal Lassa fever is relentless, with progression of the signs and symptoms culminating in the onset of shock and death. In survivors, symptoms and viremia persist until 2 to 3 weeks after onset when there is defervescence accompanied by the disappearance of virus from the blood. Pericarditis may occur in early convalescence, particularly in male patients. A case of polyserositis and recurrent pericarditis with constriction has been reported, which suggests that such complications should be sought more carefully.⁹³

Neurologic disease is not usually a dominant clinical manifestation in Lassa fever, although aseptic meningitis, encephalitis, global encephalopathy with seizures, and more subtle neurologic

problems are well described.^{46,47,213} Cerebellar ataxia in convalescence is an uncommon but interesting occurrence. In convalescence, deafness is common; this is an important feature of Lassa fever because it impacts the community and provides an important diagnostic clue.⁷⁵ Late in the course of disease or early in convalescence, unilateral or bilateral hearing loss was noted in 29% of prospectively studied patients.⁴⁷ No treatment is available, and the effects may be transitory or often permanent. The auditory patterns and clinical course resemble idiopathic nerve deafness.¹²⁹

The clinical laboratory provides few clues to the diagnosis. The leukocyte count can be low, normal, or modestly elevated. Platelet counts are generally normal but may be modestly decreased.⁹³ Albuminuria is common. AST is usually at least mildly elevated, and the degree of elevation, which parallels the viremia, is a useful predictor of mortality.¹⁰⁵ Patients with AST values in the hundreds or thousands are at considerable risk of dying, even with ribavirin treatment. Chest radiography may show infiltrates, pleural effusions, or, more commonly, no abnormalities. Electrocardiographic findings are often nonspecifically abnormal.⁴⁶

Lassa fever should be suspected in virtually any febrile patient returning from endemic areas of Africa, particularly after a rural sojourn in Nigeria, Sierra Leone, Liberia, Guinea, or another West African country. Lassa fever continues to be the most often imported VHF into Europe and the United States.^{5,204} Within a few days of onset, classical Lassa fever progresses to prostration and the other symptoms described previously, often including pharyngitis, retrosternal pain, gastrointestinal complaints, and proteinuria. However, mild or atypical cases can be diagnosed or excluded only with appropriate laboratory tests. Differential diagnoses include malaria, shigellosis, leptospirosis, rickettsial disease, relapsing fever, and typhoid; if doubt exists, these entities should be treated empirically.

Argentine Hemorrhagic Fever

Argentine hemorrhagic fever (AHF) begins insidiously with fever and malaise. Headache, myalgia, epigastric pain, and anorexia are common. Within 3 to 4 days, these symptoms give way to more severe prostration, nausea and vomiting, dizziness, and early indicators of vascular damage. The earliest signs are conjunctival injection, flushing over the head and sometimes upper torso, petechiae, and mild hypotension. Tremor of the tongue and hands is common and may resemble cerebellar disease. In the more severe cases, mucous membrane hemorrhages and ecchymoses at needle puncture points develop; shock supervenes and, with the hemorrhages, is an indicator of a poor prognosis. In some cases, there are extensive neurologic signs, including coma and convulsions; these cases also have a high mortality.¹⁹³ Usually around days 10 to 13, patients begin to improve as the appearance of immunofluorescence assays (IFAs) and neutralizing antibodies signals the onset of the immune response.⁴⁹ Overall case fatality is 30% without therapy. Convalescence often lasts several weeks with fatigue, dizziness, and hair loss.

Clinical laboratory findings are quite helpful in the diagnosis of AHF. Leukopenia, thrombocytopenia, and proteinuria are present in virtually all patients with the disease and may be early manifestations. AST and alanine transaminase are usually normal or slightly elevated. The electrocardiogram may be

nonspecifically abnormal, and chest radiography is usually normal in the absence of secondary infections.

Bolivian and Venezuelan Hemorrhagic Fevers

Bolivian hemorrhagic fever (BHF) resembles AHF clinically, just as the virus is closely related phylogenetically to JUNV.^{104,217} Mortality is about 25% to 35%. Early information from the San Joaquin epidemic suggested that most MACV infections resulted in disease sufficiently severe to be remembered as BHF¹³⁴; however, surveys in the endemic region of the Beni have found enzyme-linked immunosorbent assay (ELISA) immunoglobulin G (IgG) antibodies in persons with no previous history of BHF.

Venezuelan hemorrhagic fever also has a clinical spectrum similar to that of AHF, with thrombocytopenia, bleeding, and neurologic involvement being prominent.⁵⁰ Sore throat and pharyngitis were noted with some frequency among initial cases, and deafness has occurred in convalescence. Although reported cases have had a somewhat higher mortality (34%), it seems likely that with increased case finding, milder cases may be detected. Normal inhabitants of the endemic area have antibody prevalence rates of 0.1% to 3% and those of household contacts at 10.5%.

Sabia Virus Infection

Sabia virus was isolated from a fatal case of hemorrhagic fever presenting in Sao Paulo, Brazil, in 1990.¹³⁰ Because of the extensive liver necrosis associated with the clinical presentation, yellow fever was a leading diagnosis; however, it was excluded virologically. Later, the virus was shown to be an arenavirus, and a laboratory worker performing the studies developed severe disease resembling AHF.²²⁶ This virus once again infected a virologist in 1994, resulting in a febrile, leukopenic, thrombocytopenic syndrome that was promptly treated with intravenous ribavirin. There was an apparent clinical and virologic response. The reservoir remains unknown; it is presumed to be a rodent found around the small community of Sabia outside Sao Paulo, where the only known natural infection occurred. Without additional information, it must be assumed that this virus has a high morbidity and mortality as well as the aerosol infectivity expected from an arenavirus.

Whitewater Arroyo Virus

WWAV was first described as a zoonotic persistent infection in woodrats (*Neotoma albigula*) in New Mexico.⁷⁹ This and related reservoirs are widely distributed throughout the southwestern United States. The virus is most closely related to Tamiami virus, an arenavirus originally found in cotton rats (*Sigmodon hispidus*) in South Florida.³⁴ Little evidence for human infection or disease with either of these North American arenaviruses was found until the period from June 1999 to May 2000. Two fatal cases with a clinical picture suggesting acute hemorrhagic fever were reported to have preliminary evidence of acute WWAV infection.³³

Other Arenavirus Infections

Surveys of potentially exposed laboratory workers and residents of endemic areas indicate that most arenaviruses are infectious for humans. In most cases, actual infections have not been observed for their clinical effects, thus information about the consequences is relatively limited. The newly described Argentine arenavirus—Oliveros—provides an example.¹⁵³ This virus

TABLE 43.3 Duration of Viremia After Infection of Rodent Reservoirs with Arenaviruses

Virus	Age of infection and subsequent viremia		
	Fetal	Neonatal	Adult
LCM, Lassa	Lifelong	Lifelong	Transient
Junin, Machupo	Fetal death	Lifelong	50% lifelong 50% transient
Latino, Tamiami	?	Transient	Transient

LCM, lymphocytic choriomeningitis.

circulates in the same agricultural zones as JUNV and LCMV; however, the dark bolo mouse (*Bolomys obscurus*) is its natural reservoir. Even though these rodents comprise about 4% of the captures during longitudinal studies of small mammals in agricultural areas and one-fourth are infected, no antibodies were detected in 200 normal residents of the area or in 100 patients suspected of having AHF but found to be seronegative to JUNV. Nevertheless, it remains an open question whether this virus might not be pathogenic for humans.

Laboratory workers provide another source of information concerning arenavirus pathogenicity, because these viruses are quite infectious as small-particle aerosols. PICV has caused numerous laboratory infections without any overt disease.²⁹ Flexal virus has resulted in two symptomatic laboratory infections and should be regarded as potentially dangerous. TACV has also resulted in a single example of febrile disease with mild CNS symptoms (J. Casals, personal communication).

Little is known about the pathogenicity of OW arenaviruses other than LCMV and LASV. They are usually assumed to be less pathogenic for humans than LASV, based on their low virulence for monkeys and guinea pigs.^{173,230} They are studied at biosafety level 3 (BSL3) but with additional precautions to avoid aerosols of the substantial amounts of virus shed from infected animals.

Maternal and Fetal Infections

Several arenaviruses infect the fetus of the natural host when pregnant rodents are viremic. In some cases, this results in no damage to the developing embryo; however, in other situations, there may be fetal death (Table 43.3). Thus, it is not unexpected that maternal infections of nonreservoir rodent species may also lead to fetal infections. The extent of fetal invasion in infected humans is surprisingly high as well, and the impact on the fetus is often severe (Fig. 43.9). LCMV infection of the fetus has been associated with both fetal death at early stages of development and fatal neonatal infection.^{112,235} An association between maternal infection with LCMV and neonatal hydrocephalus with chorioretinitis was identified in Lithuania²⁰⁹; isolated cases have also been reported from Germany and France.⁴⁰

It is becoming increasingly apparent that LCMV is an important cause of fetal abnormalities in the United States. One report described the unusual occurrence of this syndrome in twins.¹² Additional cases have been reported, primarily from the midwestern and southwestern states.^{7,13,14,17,235} The emerging picture from recent observations in the United States and Europe is of a congenital infection that follows symptomatic acute febrile disease or asymptomatic infection of the mother

FIGURE 43.9. T1-weighted magnetic resonance imaging (MRI) scan of the brain of a 10-month-old child with congenital lymphocytic choriomeningitis virus infection. The child has severe developmental delay, spastic quadriplegia, and medically intractable epilepsy. The MRI scan reveals microcephaly, a lissencephalic frontal lobe (A), and hypoplasia of the corpus callosum (B), the brain stem (C), and the cerebellum (D). (Courtesy of D. Bonthius, University of Iowa.)

in mid- to late pregnancy. The fetus is severely affected with combinations of psychomotor retardation, microcephaly, hydrocephaly, visual loss, and seizures, often with evidence of aqueductal stenosis, periventricular calcifications, and chorioretinitis. The infants are not known to be chronically infected but may have a somewhat unusual antibody pattern.²¹⁰ Any child with CNS or ocular disease who does not have clear-cut evidence of intrauterine infection with one of the TORCH pathogens (toxoplasmosis, rubella, cytomegalovirus, herpes) should be evaluated for LCMV infection.

South American Hemorrhagic Fevers

Any patient from known endemic areas in South America should be under suspicion if fever, dizziness, and myalgia are accompanied by leukopenia, thrombocytopenia, and proteinuria. The relatively frequent discovery of “new” arenaviruses in the Americas implies that suggestive findings in patients with rural exposure or rodent contact anywhere in the Americas should lead to the consideration of arenavirus disease. Influenza, hantavirus pulmonary syndrome, and other febrile, myalgic diseases, as well as the more severe conditions noted for Lassa fever, enter into the differential diagnosis.

LABORATORY DIAGNOSIS

Lymphocytic Choriomeningitis

During the acute febrile phase, virus isolation from blood is the best approach. Viremia may also be detectable during the meningitic phase, although then the CSF may be more productive.^{21,67} Most clinical isolates of LCMV will be lethal for intracranially inoculated mice or intraperitoneally inoculated guinea pigs; however, some strains will require back challenge with a known virulent LCMV strain or antibody measurement to demonstrate the presence of LCMV in the original

inoculum; mice can also be injected with endotoxin to provoke lethality.⁹⁷ Isolation in cell culture (e.g., Vero cells) is less expensive, less hazardous, and less likely to suffer cross-contamination, although it is probably slightly less sensitive than animal inoculation. Polymerase chain reaction (PCR) tests applied to CSF have also shown promise.¹⁶⁷ Antibody is often present in serum and/or CSF during acute cases, and ELISA and IFA for immunoglobulin M (IgM) have been widely used to detect it.^{51,69,123,127} Neutralizing antibodies appear late after onset and are technically demanding to demonstrate, lessening their diagnostic importance.^{1,123} Complement fixation (CF) tests are relatively insensitive, and antibodies disappear quickly; high CF titers are believed to indicate recent infection. The optimal test for serosurveys needs to be established by careful comparison of the major candidates: ELISA, IFA, and neutralization.

Lassa Fever

LASV is easily isolated from blood or serum during the febrile phase of the disease up to 14 or more days after onset, even after the appearance of IFA antibody. Virus can also be detected in necropsy tissues.^{77,105} Vero cell cultures examined by IFA allow a diagnosis in 5 to 7 days or sooner. LASV antigen can be detected by ELISA capture in serum within 4 hours of beginning testing, and as it becomes negative, IgM antibodies appear.¹⁶ Antigen detection by ELISA is robust and reliable in rapidly fatal cases, even if the specimens are not handled properly for virus isolation. Reverse transcriptase PCR is also a sensitive test for virus RNA, being positive in the blood of 23 of 29 patients at admission and of 29 of 29 patients by the third day of hospitalization.^{53,221}

Antibody can be detected by either CF, IFA, or ELISA. IFA utilizing LASV-infected Vero cells as substrate is widely used. Interpretation is subjective, and discrepancies between laboratories are common. IFA IgG “seroreversion” has been reported and believed to represent loss of antibody by previously seropositive individuals.^{16,100,145} Lassa IgG and IgM can also be detected by ELISA.¹⁶³ ELISA IgM titers appear earlier and persist longer than IFA IgM titers. IgG ELISA antibody persists for long periods, whereas IFA antibody appears to wane below detectable limits within several years.

South American Hemorrhagic Fevers

Similar to LASV, Junin, Machupo, Guanarito, and Sabia viruses are infectious by aerosol, and human and rodent specimens should be processed with appropriate precautions in BSL4 laboratories. Virus can be isolated from blood or serum during the acute febrile phase until 10 to 12 days after onset by inoculation of newborn hamsters or mice.²⁵ Inoculation of cell cultures (Vero, BHK-21) is safer and more easily performed under the required BSL4 conditions. Co-cultivation of peripheral blood mononuclear cells with Vero cells seems to be more sensitive than suckling mouse or Vero cell inoculation for the isolation of JUNV from AHF patients.⁴ Virus can also be isolated from necropsy tissues, except from the brain. In rodent studies, virus is readily isolated from blood, urine, throat swabs, and autopsy tissues.^{106,107} Antigen-capture ELISA allows detection of viral antigen in blood, serum, or tissue homogenates. These tests could be used for acute diagnosis of patients suspected of having Junin, Machupo, Sabia, or Guanarito, and they are often the first available diagnostic result in rapidly fatal cases when

patients die before the appearance of antibody. Antigen detection is also possible in rodent urine, blood, and throat swabs during ecologic surveys.¹⁵⁴

Serologic diagnosis of AHF and BHF is usually made by CF^{134,233} and IFA.^{139,165,176} The lack of specificity and/or sensitivity of these tests is often a major problem. The plaque neutralization test can distinguish between antibodies to MACV and JUNV and is used for evaluation of convalescent plasma units intended for therapeutic use in AHF.⁶⁴ The ELISA test is the most useful and practical for rapid detection of IgG and IgM antibodies in a clinical setting and seroepidemiologic surveys.^{81,98} The antibodies detected by ELISA persist more than 30 years in some cases. Guanarito and Sabia IgG and IgM antibodies can also be detected by IFA and/or ELISA.

TREATMENT

Medical Management

Supportive therapy is important in the management of patients with arenaviral hemorrhagic fevers.^{174,175} Avoidance of travel and general trauma, gentle sedation and pain relief with conservative doses of opiates, the usual precautions for patients with bleeding diatheses (e.g., avoiding intramuscular injections and acetylsalicylic acid), and careful maintenance of hydration are indicated. Bleeding should be managed by platelet transfusions and factor replacement as indicated by clinical judgment and laboratory studies.

Management of shock is difficult. Modest increases in hematocrit indicate a generalized vascular permeability problem, although not of the magnitude seen in diseases such as hantavirus pulmonary syndrome⁵⁶; nevertheless, vigorous infusion of crystalloid carries a high risk of pulmonary edema. Cautious administration of fluids and early use of pressors is indicated. Because of the low cardiac output seen in the Pichinde guinea pig model of arenaviral hemorrhagic fever, and based on clinical experience with the human disease, careful monitoring is important and Swan-Ganz catheterization is desirable.

Containment

Patients with arenaviral hemorrhagic fevers are believed to pose a minimal risk of contagion in the early stages of disease. As the process continues, more extensive viral infection of target organs and increasing blood virus titers may increase the opportunities for dissemination. Nosocomial outbreaks and infection of multiple contacts have occurred; however, they are distinctly uncommon and the index patient has generally been severely ill at the time of the incident.^{36,111} The most dangerous exposure is parenteral and must be avoided through staff training. Thus, patients with these diseases should be treated in mask, gown, and glove isolation. Protection to caregivers and other patients should be enhanced by the addition of respiratory protection against small-particle aerosols.^{10,71} Close personal contacts should be monitored for fever for a period of 3 weeks. The patient may continue to excrete virus in urine or semen for weeks after recovery, thus body fluids should be monitored for infectivity before the patient is released. Meanwhile, a program of counseling that emphasizes the addition of disinfectant to toilets before use and protection used with sexual partners should be followed. Special precautions are indicated when blood and other body fluids are handled in the clinical laboratory.⁵⁸

Antiviral Drugs

Although several compounds have shown *in vitro* efficacy, only the guanosine analog ribavirin has had practical application. Although the mechanism of action is unknown, all arenaviruses tested have been inhibited in cell culture by similar concentrations of ribavirin, and the drug is effective in all arenaviral hemorrhagic fever models in which it has been studied.^{99,109,111,204,212} Ribavirin-treated experimental infections with MACV or JUNV have sometimes led to a late neurologic disease; however, activity against the visceral form of the disease has been a uniform finding. The drug is efficacious in Lassa fever and is the therapeutic agent of choice in that disease. Ribavirin has been of use principally in Lassa fever patients with a poor prognosis, usually being reserved for those with an AST value higher than 150. Preliminary results with ribavirin have been positive in AHF.⁶⁵ Anecdotal data on early treatment of human Machupo and Sabia infections have been promising.^{11,111}

Ribavirin has been considered for the prophylaxis of persons exposed to arenaviral hemorrhagic fevers. In experimental studies of Pichinde- or Lassa-infected guinea pigs, prophylaxis for periods such as 7 to 10 days only delayed the onset of acute disease by a similar period of time. However, drug administration for 14 days prevented disease.^{133,212,216} In the case of JUNV, prophylaxis of guinea pigs for 14 to 21 days prevented acute disease, although it did not prevent JUNV entering the CNS and causing fatal encephalitis.¹⁰⁹ Thus, high-risk exposures to arenaviruses are probably best managed by expectant treatment at the first sign of fever rather than dealing with the uncertainties of prophylaxis and its small but significant risk.

Passive Antibody

Therapy of JUNV infections with convalescent plasma has been carefully studied in humans and experimental animals and is quite efficacious, with reduction of mortality from 15% to 30% and to 1% to 2% if initiated within the first 8 days of illness.^{64,136} The administration of convalescent plasma (usually two to three units, depending on the neutralizing titer) is the treatment of choice. About 10% of these patients will return 3 to 6 weeks later with neurologic signs such as fever, headache, cerebellar tremor, and cranial nerve palsies. This late neurologic syndrome is usually self-limited. Serum antibody titers peak later and at a higher level, and serum-to-CSF antibody ratios are increased in comparison with those in patients without this syndrome, suggesting the prior invasion of the CNS by virus. Late eradication of virus by T cells may be a factor in its pathogenesis. The syndrome resembles other experimental arenavirus neurologic diseases seen after passive antibody therapy.^{57,110} The *in vitro* neutralization characteristics and limited studies in animal models suggest that passive antibody therapy would probably be useful in Machupo and Guanarito virus infections.⁵⁷

LASV infections are more difficult prospects for antibody therapy because, based on animal studies, the volumes of plasma needed are large; experimental studies of IgG for intravenous administration indicate that this could be a useful means of treatment only if highly active preparations were available.^{101,102,173} The future of antibody therapy in any of these diseases lies in development of standardized monoclonal antibody preparations of proven efficacy.^{194,200} Experimental studies of passive protection by monoclonal antibodies have been successful in LCMV.^{8,9,234}

Central Nervous System Disease

Ribavirin penetrates poorly into the CSF, and no established antiviral therapy exists for arenavirus infection in the CNS. LCMV ependymal infection and inflammation may cause acute hydrocephalus and a need for surgical shunting.¹¹⁸ Steroids have not been evaluated in this condition. The late neurologic syndrome seen after immune plasma treatment of AHF is generally self-limited and should be treated expectantly.⁶⁴

Vaccines

Novel Approaches for Vaccine Development

The JUNV live attenuated Candid #1 strain was generated by serial passages of the XJ strain of JUNV in mouse brain. The safety, immunogenicity, and protective efficacy of Candid #1 was demonstrated in preclinical studies in both guinea pigs and rhesus macaques.¹⁴⁸ Vaccination campaigns targeting agricultural workers in the JUNV endemic area have shown Candid #1 to be an effective and safe vaccine in humans,¹³⁷ and it was licensed in 2006 for use exclusively in Argentina. There are, however, some concerns related to the limited information about the genetic composition of the Candid #1 vaccine and still poor understanding regarding the viral genetic determinants of JUNV attenuation. The potential genetic instability of Candid #1 vaccine was illustrated by a 1,000-fold range of virulence among Candid #1 clones isolated from blood of vaccinated rhesus monkeys.⁶³ The lack of clearly established genetic markers associated with Candid #1 attenuation complicates the assessment of the emergence of potentially pathogenic variants during the preparation of Candid #1 vaccine. Reverse genetics approaches should facilitate the generation of molecular clones of genetically well-defined live attenuated vaccine strains with the ability to induce strong protective immunity.^{18,61,62}

Antiviral Drugs

The observation that a chimeric Vesicular Stomatitis Virus-LCMV vaccine was highly attenuated but induced a strong protective immune response¹⁸ led to examine the potential of LCMV as a viral vector system for immunization against non-LCMV antigens of interest. Thus, rLCM viruses where GPC was replaced by a protein antigen of interest were able to induce good immune responses against the foreign protein while immunized mice remained free of disease symptoms.⁷⁴ However, pre-existing immunity against LCMV in human populations may limit the use of LCMV as a vaccine platform. Notably, trisegmented rLCMV expressing high levels of non-LCMV GOIs have been found to exhibit attenuation *in vivo* while exhibiting sufficient levels of replication to induce strong protective immunity against a subsequent LCMV lethal challenge.⁶¹ This approach could be implemented to increase the safety of Candid #1. Moreover, the geographic restricted distribution of JUNV should eliminate pre-existing immunity as a barrier for the use of Candid #1 as a vaccine platform against other pathogens.

LASV poses the main concern among arenaviruses known to cause disease in humans. This is owing to its vast endemic region and size of the population at risk. Therefore, vaccination of the population at risk of LASV infection would be an important task in public health. Currently, there are not well-established attenuated strains of LASV, which prevents a vaccination approach similar to the one based on Candid #1 against Junin Virus. Nevertheless, several approaches have been pursued,

aimed at the development of an LASV vaccine including DNA immunization approaches¹⁸⁶ and different vector-based vaccines. Recombinant vaccinia viruses expressing LASV NP or GP have been shown to provide cell-mediated immunity against LASV in guinea pigs and nonhuman primates.⁷² However, the high prevalence of human immunodeficiency virus (HIV) within the LASV endemic region would pose some risk concerns of using a vaccinia virus-based vectors. Both alphavirus- and vesicular stomatitis virus (VSV)-based vectors^{83,182} have been used to induce protective immunity against LASV. Likewise, Venezuelan equine encephalitis virus¹²¹ and the 17D yellow fever vaccine²⁶ have shown promising results as potential candidate vectors for LASV vaccines. In addition, the induction of heterologous immunity by using a closely related but less pathogenic virus has been explored for the development of an LASV vaccine. Thus, a reassortant (called ML29) between MOPV, an OW arenavirus considered to be nonpathogenic to humans, and LASV has shown some promising results³⁸; however, detailed safety and efficacy studies have not been completed. An alternative approach for the development of a Lassa fever vaccine would be the use of reverse genetics to generate biologically contained versions of LASV in a similar way as described for Ebola virus⁸⁶ and influenza.¹⁴¹ Recent work with LCMV has provided strong support for the feasibility of this approach⁷⁴ to generate a safe and effective LASV vaccine. Likewise, the use of live attenuated trisegmented Candid #1 expressing relevant LASV T-cell epitopes could be used to induce protective immunity against JUNV and LASV. Finally, a fully synthetic approach to vaccine design has recently been proposed that builds on the observation of conserved peptide epitopes recognized by cytotoxic T lymphocytes directed against LCMV antigens.^{23,24} This system, if successfully established, offers the potential for a broadly cross-reactive arenavirus vaccine.¹¹³

Novel Targeting Strategies

The prophylactic and therapeutic value of the nucleoside analog ribavirin against several arenaviruses is well supported by both cell culture and whole organism studies. Thus, ribavirin reduced both morbidity and mortality in humans associated with LASV infection, and experimentally in MACV and JUNV infections, if given early in the course of clinical disease.⁴⁸ However, the need for intravenous administration for optimal efficacy and significant side effects including anemia and congenital disorders pose some significant limitations to the use of ribavirin. In addition, the mechanisms by which ribavirin exerts its antiarenaviral action remain poorly understood but are likely to involve different steps of the virus life cycle, which may complicate rational design to improve drug specificity.¹⁶⁸ Recent high-throughput screening (HTS) identified a potent small molecule inhibitor of TACV and several other NW arenaviruses.²² Likewise, cell-based HTS based on the use of pseudotyped virion particles bearing the GP of highly pathogenic arenaviruses identified several small molecule inhibitors of virus cell entry mediated by LASV GP.¹²⁰ These findings illustrate how screening of complex chemical libraries using appropriate assays represent a powerful tool to identify candidate antiviral drugs with highly specific activities. Progress in arenavirus reverse genetics is allowing investigators to dissect each of the steps of the virus life cycle to uncover novel targets and develop screens to identify drugs directed against specific steps of the arenavirus life cycle. Two

particularly promising possibilities are targeting virus budding and the S1P-mediated processing of arenavirus GPC.

For many characterized viral budding proteins, their budding activity requires interaction, via its L domains, with specific host cellular factors including members of the endosomal sorting complex required for transport (ESCRT) machinery within the endosomal/multivesicular body pathway of the cell. The generation of recombinant arenaviruses expressing appropriate tagged versions of Z should facilitate studies aimed at the identification and characterization of the Z–host cell protein interactions involved in arenavirus budding in the context of the natural course of infection of the virus. Knowledge from these studies may uncover novel targets and facilitate the development of screening processes to identify small molecules capable of disrupting these interactions and thereby interfering with virus propagation. The ESCRT machinery participates in various processes required for normal cell physiology^{37,158}; therefore, long-term disruption of the normal function of ESCRT components is likely to result in unacceptable levels of toxicity. However, arenavirus-induced hemorrhagic fevers are acute disease processes, and it is plausible that short-term inhibition of ESCRT members to combat an acute hemorrhagic fever arenaviral disease may cause only limited toxicity.

S1P-mediated processing of arenavirus GPC is strictly required for production of infectious progeny and cell-to-cell virus propagation, and thereby for both intra- and interhost virus propagation.¹¹⁶ Notably, studies with LCMV and JUNV indicated that the appearance of viral variants capable of growing independently of S1P-mediated processing of GPC appears to be a highly unlikely event. These findings strongly support the idea that inhibitors of S1P-mediated processing of GPC would represent promising antiarenaviral drug candidates.^{188,189} S1P is encoded by the membrane-bound transcription factor protease site 1 gene and is an endoplasmic reticulum/early Golgi membrane-anchored serine protease.^{196,197,207} S1P is involved in proteolytic processing of a defined set of cellular proteins. The key role of S1P in the regulation of lipid metabolism and cholesterol biosynthesis has raised significant interest in developing specific inhibitors of S1P activity. Several peptide and nonpeptide-based S1P inhibitors have been documented; however, their lack of cell permeability would pose severe limitations to their use as antiviral drugs. Recently, decanoylated chloromethylketone-derivatized peptides containing the RRLI recognition sequence of S1P have been shown to act as potent suicide inhibitors of S1P catalytic activity. These drugs cause irreversible inhibition of the catalytic activity of S1P against host cell and pathogen-derived targets, which might result in unacceptable levels of cellular toxicity. Recently, the small molecule PF-429242 was reported to be a potent S1P inhibitor both *in vitro* and in cell-based assay.^{91,92} In addition, PF-429242 was shown to inhibit efficiently S1P-mediated processing of arenavirus GPC, which correlated with the drug's ability to interfere with propagation of both LCMV and LASV in cultured cells.²²⁴

PERSPECTIVES

Since the fortuitous discovery of LCMV more than 70 years ago, arenaviruses have provided important model systems for the study of host–virus interactions. The study of these models has illuminated a wide range of principles, including persistent

infection, virus-induced immunopathologic disease, cytotoxic T-cell recognition, and immunological memory. Despite this wealth of knowledge, and even though arenavirus infections of humans remain a significant public health risk in much of the world, the prospects for control of these diseases remain remote because of poor diagnostic protocols and sparse resource allocation to vaccine development and other control measures. Recent laboratory developments have advanced our understanding of arenavirus structure and biology, and new vistas have been opened into arenavirus prevalence and distribution as a result of the application of deep sequencing protocols applied to this interesting group of agents. The application of new approaches to antivirals and vaccines targeting arenaviruses may provide a useful model for many localized viral diseases where the knowledge but not the financial incentive for control or eradication exists.

INTRODUCTION AND HISTORY

Basic Features of the *Reoviridae*

Members of the *Reoviridae* form nonenveloped virions composed of 1 to 3 concentric protein shells. The genomes of these viruses consist of 9 to 12 discrete segments of double-stranded RNA (dsRNA). Much of what is known about the *Reoviridae* comes from studies of orbiviruses, orthoreoviruses, and rotaviruses. Although these and other *Reoviridae* members display important structural and biological differences, there are several properties held in common across the family.

The dsRNA gene segments of the *Reoviridae* viruses are not thought to leave the inner capsid particle. Enzymes that catalyze RNA transcription, capping, and replication are contained within the inner capsid, which serves as the site for the RNA synthetic activities. The messenger RNA (mRNA) transcripts are capped but not polyadenylated. The infectious cycle is entirely cytoplasmic and occurs for the most part in neooorganelles that are termed viral factories, viral inclusion bodies, or viroplasms. These viruses are sensed by the innate immune system and activate signaling cascades that induce an antiviral state or evoke apoptosis.

Discovery of Mammalian Reoviruses

Reoviruses were first isolated from stool specimens of children during the 1950s by Albert Sabin, Leon Rosen, and their colleagues.^{412,423} Reovirus is an acronym for respiratory enteric orphan virus; infections of humans by reovirus usually involve the respiratory and intestinal tracts with minimal or no associated disease symptoms (therefore the virus is an “orphan”). In the early 1960s, Peter Gomatos and Igor Tamm noticed that the inclusion bodies in reovirus-infected cells fluoresce greenish-yellow when stained with acridine orange, whereas single-stranded RNA (ssRNA) fluoresces orange.¹⁹⁸ Using chemical

and physical studies, the viral genome was demonstrated to consist of dsRNA.^{40,197,347} Reoviruses were the first dsRNA viruses to be described.

The *Reoviridae* now includes 15 genera of dsRNA viruses that infect a wide variety of plants, animals, fungi, and protozoa (Table 44.1). The mammalian orthoreoviruses are the type species of the *Orthoreovirus* genus, which also contains viruses that infect birds and reptiles. The term “reovirus” refers to the mammalian orthoreoviruses and will be used as such in this chapter.

Pathogenic Reoviridae Viruses

Some members of the *Reoviridae* are pathogenic. Rotaviruses are responsible for gastroenteritis in animals and humans; they cause a large proportion of childhood gastroenteritis and are a major cause of infant illness and death in the developing world (see Chapter 45). Orbiviruses are transmitted by arthropod vectors and replicate in both mammalian and arthropod hosts (see Chapter 46). The best-studied orbivirus is bluetongue virus, an economically significant pathogen of sheep and cows named for a symptom affecting sick animals. Coltiviruses are also transmitted by arthropod vectors, and the prototype member, Colorado tick fever virus, can cause neurologic disease in humans. Aquareoviruses infect fish and mollusks. Fusogenic orthoreoviruses appear to cause pulmonary disease in humans.

Reovirus as a Model for Studies of dsRNA Virus Replication and Pathogenesis

Reoviruses are useful experimental models for studies of viral replication and pathogenesis. Studies of reovirus RNA synthesis were the first to describe the methylated cap structure that modifies most eukaryotic mRNA molecules and is required for normal translation;^{178–180} this work was done using RNAs synthesized *in vitro* from reovirus cores. Genetic approaches used to study the pathogenesis of reovirus in mouse models of infection and disease led to the discovery that phenotypic differences in

specific steps in the virus–host encounter segregate with specific gene segments.^{254,498,515} Reovirus was the first virus shown to traverse the intestinal mucosa by transcytosis across microfold (M) cells⁵³⁴ and undergo proteolytic disassembly catalyzed by endosomal cathepsins.¹⁵⁶ More recent developments have led to the deployment of reovirus as an oncolytic adjunct to cancer therapy^{475,493} and the potential use of reovirus as a vaccine vector through the application of plasmid-based reverse genetics.²⁶¹

TAXONOMY

dsRNA Viruses

There are nine taxonomic families of dsRNA viruses: the *Birnaviridae*, *Chrysoviridae*, *Cystoviridae*, *Endornaviridae*, *Hypoviridae*, *Partitiviridae*, *Picobirnaviridae*, *Reoviridae*, and *Totiviridae*. The *Birnaviridae*, *Picobirnaviridae*, and *Reoviridae* infect vertebrates; the *Picobirnaviridae* and *Reoviridae* infect mammals, including humans. The nine families are distinguished by genome organization, coding strategy, particle structure, and host range, among other properties. Differences in RNA-dependent RNA polymerase (RdRp) sequences suggest independent evolutionary lineages of dsRNA viruses from positive-sense RNA virus ancestors.²⁶⁷ Similarities beyond the existence of dsRNA genomes also suggest common ancestry, most notably in the organization of the capsid components. Interestingly, not all dsRNA viruses encode capsids. Members of the *Hypoviridae* transfer their genomes vertically during propagation of their fungal hosts.¹²⁶

Family Reoviridae

The *Reoviridae* is the largest and most diverse family of dsRNA viruses. The viral particles display icosahedral symmetry with a diameter of 65 to 80 nm. The protein capsid is organized as one, two, or three concentric capsid layers, which surround the dsRNA segments of the viral genome. Members of some genera have filamentous attachment proteins, but most do not. The viral RNA species are usually monocistronic, although some segments have two or three in-frame initiation codons that lead to expression of additional open-reading frames (ORFs). Alternative out of frame ORFs or nonoverlapping ORFs are occasionally present. Proteins are encoded by only one strand of each duplex (the mRNA species).

The 15 genera of the *Reoviridae* are divided into two groups based on particle morphology (Table 44.1). The *Sedoreovirinae* subfamily includes genera containing “smooth” viruses that are almost spherical in appearance, including *Cardoreovirus*, *Mimoreovirus*, *Orbivirus*, *Phytoreovirus*, *Rotavirus*, and *Seadornavirus*. The *Spinareovirinae* subfamily includes genera containing viruses with large “spikes” or “turrets” at the 12 icosahedral vertices of the virus or core particle, including *Aquareovirus*, *Coltivirus*, *Cypovirus*, *Dinovernavirus*, *Fijivirus*, *Idnoreovirus*, *Mycoreovirus*, *Orthoreovirus*, and *Oryzavirus*. The overall fold of several of the major inner and outer capsid proteins of *Reoviridae* members is similar, despite the absence of primary sequence identity.

The inner protein layer of the *Sedoreovirinae* (smooth) viruses has T=2 symmetry and is relatively fragile. This structure is surrounded by an additional protein layer, which has T=13 symmetry, to form the transcriptionally active core particle. These double-layered particles are surrounded by an

FIGURE 44.1. Schematic of reovirus particles with protein composition. Diagram of a cross-section from virions, infectious subviral particles (ISVPs), and core particles showing the arrangement of the viral structural proteins in the double-layered shells of virions, the formation of ISVPs by removal of $\sigma 3$, cleavage of $\mu 1$, and rearrangement of $\sigma 1$; and the conversion to core particles by removal of the $\mu 1$ fragments, loss of $\sigma 1$, and opening of the $\lambda 2$ turret.

outer-capsid shell, giving rise to triple-layered particles. In contrast, the transcriptionally active core particle of the *Spinareovirinae* (turreted) viruses appears to contain only a single complete capsid layer, which has been interpreted as having T=1 or T=2 symmetry, to which the spikes are attached. Despite these different interpretations, the structure of the innermost complete capsid layer is almost identical for members of both the *Sedoreovirinae* and *Spinareovirinae*. In most cases, the core is surrounded by an additional protein layer with T=13 symmetry that forms the outer capsid, which is penetrated by the spikes that arise from the core surface. These virus particles are therefore usually regarded as double shelled (Fig. 44.1).

The innermost protein layer of *Reoviridae* viruses has an internal diameter of approximately 50 to 60 nm surrounding the 9 to 12 linear dsRNA gene segments. In the *Sedoreovirinae* viruses, the enzymatically active proteins of the virion, RdRp, NTPase, guanylyltransferase, and transmethylease, are also situated within this central structure attached to the inner surface at the fivefold symmetry axes. In the *Spinareovirinae* viruses, some of these enzymes form the turrets on the surface of the core. These hollow projections also act as conduits for the exit of nascent mRNAs synthesized by the core-associated enzymes.

Genus *Orthoreovirus*

The genus *Orthoreovirus* contains the nonfusogenic mammalian orthoreoviruses and the fusogenic orthoreoviruses, which infect a variety of vertebrate hosts. Common features of the members of the genus *Orthoreovirus* include: (1) two protein shells with core spikes at the icosahedral vertices; (2) 10 dsRNA

segments including three large (L), three medium (M), and four small (S) size-class RNA gene segments; (3) three λ , three μ , and four σ primary translation products; (4) additional small gene products encoded by a polycistronic *S1* gene segment; and (5) common serologic characteristics. Related members of the genus *Orthoreovirus* can exchange gene segments following co-infection of cells, producing viral progeny termed “reassortant viruses” containing mixtures of gene segments derived from both parents. The capacity of two strains to produce viable reassortant progeny can serve as the basis for designating species of virus within the genus.^{153,322} Nonfusogenic isolates can exchange gene segments with each other, as can fusogenic isolates, but reassortment between nonfusogenic and fusogenic viruses has not been reported.

Mammalian orthoreovirus was the first species of the family *Reoviridae* to be isolated and identified.⁴²³ The prefix “ortho-” was added to the name of the initial isolates (orthoreoviruses) and the corresponding genus (*Orthoreovirus*) to distinguish them from other members of the family, which also could be called “reoviruses.” However, in common usage the term “reovirus” refers to the mammalian orthoreoviruses.

Nonfusogenic Orthoreoviruses

Reoviruses have a wide geographic distribution, and virtually all mammals, including humans, serve as hosts for infection. Based on sequence analysis of reovirus strains isolated from a variety of mammalian hosts, there is no evidence that any of the gene segments confer host range restriction.^{88,510} Because of their near ubiquity, reoviruses are used as a marker for mammalian fecal contamination of water sources.³¹⁴ Human infections

with reovirus are common, with most children demonstrating serologic evidence of infection by the age of 5 years.⁴⁸² However, reovirus is rarely associated with disease, except in the very young. There is evidence suggesting an association between reovirus and infantile biliary atresia,^{393,499} but a causal link has not been demonstrated. Newborn mice are exquisitely sensitive to reovirus infection and have been used as the preferred experimental model for studies of reovirus pathogenesis.⁵¹⁰

Three mammalian reovirus serotypes have been identified by classical neutralization and hemagglutination-inhibition (HAI) tests. Four virus strains isolated from children in the 1950s—type 1 Lang (T1L), type 2 Jones (T2J), type 3 Abney (T3A), and type 3 Dearing (T3D)—are used most frequently as prototype strains.⁴²³ A distinct reovirus strain was isolated from a mouse in the Cameroon¹⁸ and may represent a fourth mammalian reovirus serotype. Nucleotide sequences indicate that nonfusogenic mammalian isolates are a distinct phylogenetic group within the genus *Orthoreovirus*.¹⁵³ General features of the nonfusogenic mammalian orthoreoviruses are provided in Table 44.2.

Fusogenic Orthoreoviruses

The fusogenic orthoreoviruses infect birds, mammals, and reptiles. In contrast to the nonfusogenic orthoreoviruses, fusogenic reoviruses induce the formation of large, multinucleated syncytia.¹²⁷ Fusion activity is mediated by virus-encoded, fusion-associated small transmembrane (FAST) proteins, which are not capsid components but instead expressed on the surface of infected cells.⁴⁵³ FAST proteins are small (<20 kDa), basic, acylated proteins that induce fusion in transfected cells in the absence of other viral proteins.⁶² Fusogenic members of the related genus, *Aquareovirus*, also encode FAST proteins.³⁸⁶ Extensive syncytium formation results in apoptosis and enhanced release of infectious virions.⁴²⁶ Expression of the p14 FAST protein by a recombinant vesicular stomatitis virus increases neuropathology.⁶⁹ The FAST proteins therefore likely contribute to the natural pathogenicity of the fusogenic orthoreoviruses. Other than this fusion activity, the replication strategies of fusogenic and nonfusogenic orthoreoviruses are similar.⁴²

The fusogenic orthoreoviruses are divided into four species: avian reovirus (ARV), Nelson Bay reovirus (NBV), reptilian reovirus (RRV), and baboon reovirus (BRV).⁸⁸ ARVs infect a variety of avian hosts and are important pathogens in the poultry industry, causing gastroenteritis, hepatitis, malabsorption, myocarditis, and pneumonia.²⁴⁹ Birds that survive acute systemic infection can develop joint and tendon inflammation that resembles the pathology of human rheumatoid arthritis. RRVs have been isolated from numerous reptile species, and infected animals often develop pneumonia and neurologic symptoms.⁵¹⁹ BRV was isolated from baboons with meningoencephalomyelitis in a colony in Texas.²⁸⁰ Therefore, it is an example of a fusogenic mammalian orthoreovirus. BRV virions, like those of the aquareoviruses, lack the classical sigma-class fiber protein used for cell adhesion by other reoviruses.⁵³⁷ NBV is the prototype orthoreovirus species isolated from bats; it is more closely related to ARV than to BRV, the other fusogenic mammalian orthoreovirus species.¹²⁷

Additional fusogenic bat reoviruses have been isolated,³⁸¹ one of which represents a new species that also lacks a sigma-class fiber attachment protein.⁴⁸⁷ Three fusogenic reoviruses

TABLE 44.2 General Features of Nonfusogenic Mammalian Orthoreoviruses

Genome

Double-stranded RNA (dsRNA)
Ten gene segments in three size classes (L, M, S)
Total size ~ 23,500 base pairs
Gene segments each encode one or two proteins.
Gene segments are transcribed into full-length mRNAs.
Plus strands of gene segments have 5' caps.
Nontranslated regions at segment termini are short.
Gene segments can undergo reassortment if two or more strains infect a single cell (antigenic shift).

Particles

Nonenveloped
Spherical with icosahedral symmetry
Total diameter ~ 85 nm (excluding $\sigma 1$ fibers)
Two concentric protein capsids: outer-capsid subunits in T = 13 *laevo* lattice and arrangement of inner-capsid subunits in T = 1 lattice
Eight structural proteins: four proteins in the outer capsid ($\lambda 2$, $\mu 1$, $\sigma 1$, and $\sigma 3$) and five proteins in the core ($\lambda 1$, $\lambda 2$, $\lambda 3$, $\mu 2$, and $\sigma 2$)
Subviral particles (ISVPs and cores) can be generated from fully intact particles (virions) by proteolysis.
Protein $\lambda 2$ forms pentamers that protrude from the core surface.

Replication

Occurs in the cytoplasm of host cells
Viral attachment protein $\sigma 1$ binds to two cell-surface receptors, sialylated glycans and junctional adhesion molecule-A.
Proteolysis of outer-capsid proteins $\sigma 3$ and $\mu 1$ is required for infection and can occur either extracellularly or in the endocytic compartment.
Genomic dsRNA does not exit the viral core.
Transcription and capping of viral mRNAs occur within cores; both processes are catalyzed by particle-associated enzymes.
Single-stranded, positive-sense RNAs are assorted into progeny cores.
Minus-strand synthesis occurs within assembling particles.
Mature virions are released from infected cells by mechanisms that are not well understood.
Many reovirus strains induce apoptosis of host cells.

isolated from humans with acute respiratory infections also may be of bat origin.^{96–98} These viruses appear capable of human-to-human transmission, raising concern that fusogenic bat reoviruses may be a potential source of emerging infections in humans.

PARTICLES

Particle Function

Reovirus virions are spherical, nonenveloped particles approximately 85 nm in diameter as assessed by cryoelectron microscopy (cryo-EM) image reconstructions¹⁵¹ (Fig. 44.2). Virions are formed by two concentric capsid protein shells that surround and protect the dsRNA genome. The inner-capsid shell or core particle encloses the genome, which is present in a

FIGURE 44.2. Cryo-EM image reconstructions of reovirus particles. Surface-shaded representations of cryo-EM image reconstructions of reovirus virions, infectious subviral particles (ISVPs), and cores viewed along a fivefold axis of symmetry. The color coding is based on radial density and roughly approximates the individual capsid proteins as depicted in the legend. *Yellow* corresponds to the interior of the particle. (Adapted from Dryden KA, Wang G, Yeager M, et al. Early steps in reovirus infection are associated with dramatic changes in supramolecular structure and protein conformation: analysis of virions and subviral particles by cryoelectron microscopy and image reconstruction. *J Cell Biol* 1993;122:1023–1041.)

condensed liquid crystalline form.³⁹⁴ The outer-capsid shell surrounds the core particle, which protrudes radially into the outer-capsid layer at each of the fivefold axes of symmetry.¹⁵¹

Several different morphotypes of reovirus particles are found within infected cells or can be generated *in vitro*. These include genome-containing virions, infectious or intermediate subviral particles (ISVPs), and core particles (Figs. 44.1 and 44.2) as well as their genome-lacking counterparts. In addition, less well-defined particles have been purified from infected cells and are characterized by the capacity to transcribe the genome *in vitro* (“transcriptase” particles) or synthesize a negative-stranded RNA copy of particle-associated viral mRNA (“replicase” particles).^{338,557} Physical properties of virions, ISVPs, and cores are described in Table 44.3.

Virions

Reovirus virions are relatively stable in the environment^{198,208} and maintain infectivity for years when stored below 4°C.⁴⁴ Large quantities of infectious virions can be purified from infected mouse L929 cells by Freon extraction and centrifugation in CsCl gradients.⁴⁴

Virions are composed of a genome-containing inner T=1 icosahedral core surrounded by a T=13 laevo outer-capsid layer (Fig. 44.2). The outer capsid consists of 200 heterohexameric complexes of the M2-encoded $\mu 1$ (76 kDa, 708 aa) and S4-encoded $\sigma 3$ (41 kDa, 365 aa) proteins. These complexes form a fenestrated shell that overlies the core. The outer-capsid shell is perforated at the icosahedral fivefold symmetry axes by turret-like structures formed by pentamers of the L2-encoded

TABLE 44.3 Characteristics of Common Reovirus Particle Forms			
Feature or property	Virion	Infectious subviral particle (ISVP)	Core
Buoyant density in CsCl (g/cm ³)	1.36	1.38	1.43
Sedimentation value (S)	730	630	470

Initiation and capping	Yes	Yes	Yes
Elongation	No	No	Yes

$\lambda 2$ protein (144 kDa, 1288–1289 aa). The S1-encoded $\sigma 1$ attachment protein (49–51 kDa, 455–470 aa) forms filamentous trimers that protrude from each of the $\lambda 2$ turrets. In addition to encapsidating the 10 dsRNA gene segments, virions also contain short ssRNA oligonucleotides that can constitute up to 25% of the RNA in purified virions.⁴⁴³ Most of these oligonucleotides (70%) are 2- to 9-residue products of abortive transcription and terminate with 5'-GC(U)(A).⁵³⁶ The remainder (approximately 30%) are oligoadenylates that range in length from 2 to 20 residues.⁴⁵⁵ Complete or partial atomic resolution structures are available for $\sigma 1$ trimers,^{92,395} $\sigma 3$ dimers,³⁶⁸ and $\mu 1:\sigma 3$ heterohexamers.²⁸⁹ Cryo-EM image reconstructions of reovirus virions, ISVPs, and cores¹⁵¹ (Fig. 44.2), and an atomic resolution structure of the core³⁹⁴ have been determined.

Infectious Subviral Particles (ISVPs)

Treatment of virions with chymotrypsin or trypsin using controlled conditions *in vitro*⁵⁸ or virion disassembly during infection of cells⁴⁸⁰ or in the murine intestine^{29,54} generates ISVPs (Figs. 44.1 and 44.2). These particles lack $\sigma 3$ but retain $\sigma 1$ and a proteolytically cleaved version of $\mu 1$ (see Replication—Disassembly). The loss of $\sigma 3$ and cleavage of $\mu 1$ imparts a twofold increase in infectivity of ISVPs relative to virions for reovirus strain T1L. In contrast, *in vitro* generation of ISVPs from strain T3D virions leads to a 10-fold decrease in infectivity as a consequence of additional proteolytic cleavage of $\sigma 1$.³⁴⁹ This cleavage is controlled by a sequence polymorphism in $\sigma 1$ at amino acid 249⁸⁷ and likely explains the decreased growth in the intestine and avirulence of T3D after peroral inoculation of newborn mice.⁵³ An additional intermediate particle, the ISVP*, is generated from ISVPs during infection of cells.⁸¹ ISVP*s lack the $\sigma 1$ attachment protein, have an altered conformer of $\mu 1$, and tend to aggregate. In contrast to virions and ISVPs, ISVP*s are transcriptionally active.⁷⁹ ISVP*s are formed following generation of ISVPs and thought to interact with cell membranes leading to membrane penetration and release of the core particle into the cytosol (see Replication—Membrane Penetration).

Core Particles

Like ISVPs, cores can be generated *in vitro* by treating virions with chymotrypsin or trypsin using specific conditions.⁶⁰ Such treatment removes all of the outer-capsid proteins ($\mu 1$, $\sigma 3$, and $\sigma 1$) and exposes prominent turrets formed by pentamers of $\lambda 2$. These turrets protrude from the capsid shell at each of the fivefold symmetry axes (Figs. 44.1 and 44.2) and form hollow cylinders that open to the interior of the particle. In cryo-EM image reconstructions of virions and ISVPs, the cavity within each turret is partially filled by a bulb-like structure that corresponds to a portion of the $\sigma 1$ protein¹⁵¹ (Fig. 44.2). The $\sigma 1$ bulb is held in place by flap domains present on each of the five $\lambda 2$ proteins. In cores, the flap domains of $\lambda 2$ open outwards. The interior surface of the pore formed by the $\lambda 2$ turret possesses guanylyltransferase and methyltransferase activities, which allow the turrets to function as mRNA capping complexes³⁹⁴ (see Replication—Transcription). Cores are approximately 1,000,000-fold less infectious than virions⁸⁴ as a consequence of the loss of the outer-capsid proteins, which are required for virus attachment, entry, and membrane penetration.

The T=1 core shell is formed by 120 copies of the L3-encoded $\lambda 1$ protein (142 kDa, 1275 aa) arranged in parallel

asymmetric dimers (sometimes referred to as T=2). Five copies of $\lambda 1$ (conformer $\lambda 1A$) radiate from the fivefold axes of symmetry. These molecules interdigitate with a second set of five $\lambda 1$ proteins (conformer $\lambda 1B$) to form decamers; 12 decamers form the core shell.³⁹⁴ The $\lambda 1$ shell is stabilized by 150 copies of the S2-encoded $\sigma 2$ protein (47 kDa, 418 aa), which clamps onto $\lambda 1$ at three distinct sites within each icosahedral asymmetric unit of the shell.³⁹⁴ Channels permeate the shell, with those at the fivefold symmetry axes allowing entry of NTP substrates and exit of newly synthesized viral mRNAs.

The reovirus core is described as a “molecular machine” owing to its capacity to synthesize capped viral mRNA transcripts *in vitro* when incubated with suitable substrates. During infection, particles thought to be similar to *in vitro*-generated cores initiate viral transcription after being deposited in the cytoplasm. Core particles contain 12 copies of the L1-encoded $\lambda 3$ polymerase (142 kDa, 1267 aa). Each $\lambda 3$ protein is anchored to three $\lambda 1$ proteins on the inner surface of the core and overlaps with, but is eccentric from, each of the icosahedral symmetry axes.⁵⁵⁰ In addition, cores contain approximately 24 copies of the M1-encoded $\mu 2$ protein (83 kDa, 736 aa),¹¹⁴ a polymerase co-factor. The precise location of $\mu 2$ within the core particle is not known, but one or two copies of $\mu 2$ are thought to associate with each copy of $\lambda 3$.

Empty Particles (“Top Component” Particles)

Purification of reovirus particles from infected cells *in vitro* yields a substantial proportion of particles that lack genomic dsRNA.⁴⁶³ These empty particles have a lower buoyant density in CsCl gradients and band closer to the top of the gradient in comparison to genome-containing particles, hence the designation “top component”.⁴⁴ Protease treatment of such particles can generate “empty” ISVPs and cores.

Recombinant Particles

Recombinant core-shell particles can be formed by co-expression of the $\lambda 1$ and $\sigma 2$ proteins or the $\lambda 1$, $\lambda 2$, and $\sigma 2$ proteins.⁵³⁵ Purified viral core particles prepared by *in vitro* digestion of virions with chymotrypsin or trypsin can be recoated with outer-capsid proteins $\mu 1$, $\sigma 3$, and $\sigma 1$ prepared using baculovirus expression systems.⁸⁴ Such recoated particles display infectivity similar to native virions and are useful tools for defining the consequences of lethal mutations in outer-capsid proteins on early steps in viral infection (see Genome and Coding Strategies—Genetic Complementation).

GENOME AND CODING STRATEGIES

Physical Characteristics

The reovirus genome consists of 10 discontinuous segments of dsRNA. The [+] and [–] strands of genomic dsRNA are colinear and complementary.^{40,197} The genomic dsRNA has an A-form structure with a right-handed double helix (10 base pairs per turn, 30 Å pitch, nucleotides oriented at 75° to 80° to the long axis).¹⁷

Gene Segments and Nomenclature

The 10 reovirus dsRNA gene segments are present in equimolar amounts in viral particles.⁴⁴⁴ The segments are grouped by size into large (L), medium (M), and small (S) classes according

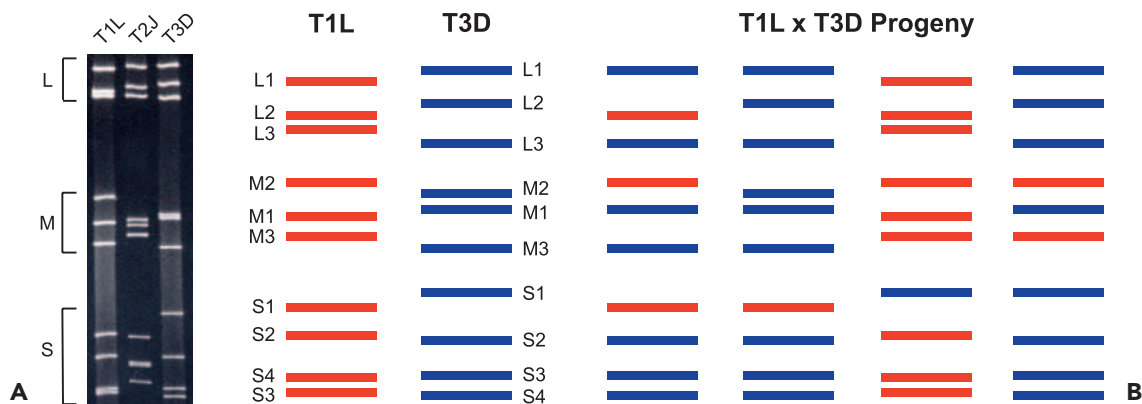

FIGURE 44.3. The segmented reovirus genome. A: Electrophoretic profiles of genomic double-stranded RNA (dsRNA) of prototype reovirus strains type 1 Lang (T1L), type 2 Jones (T2J), and type 3 Dearing (T3D). Equal numbers of reovirus particles were resolved by polyacrylamide gel electrophoresis. Viral dsRNA gene segments were visualized following ethidium bromide staining. Gene segment size classes, large (L), medium (M), and small (S), are indicated. **B:** Generation of reovirus reassortant viruses. Co-infection of cells with different reovirus strains produces a collection of progeny viruses containing various combinations of gene segments from each parent. Such viruses are generally termed “reassortant viruses.” Shown here are schematic diagrams of electrophoretic profiles of *T1L* and *T3D* gene segments along with some reassortant progeny. Gene segment identities of both strains are shown.

to their migration in polyacrylamide gels.^{195,330,444,513} There are three large (L1, L2, L3), three medium (M1, M2, M3), and four small (S1, S2, S3, S4) segments. Homologous gene segments from different reovirus isolates often migrate with different mobilities in polyacrylamide gels despite being of similar or identical length³⁸⁸ (Fig. 44.3). This property allows gene segments from different isolates to be unambiguously distinguished, which is essential for the assignment of gene segments in reassortant viruses to specific parental strains (see Genome and Coding Strategies—Reassortment). The gene segments of prototype strain T3D are numbered according to their relative mobilities in Tris/acetate-buffered gels.⁴⁴¹ Each gene segment encodes at least one protein product (Table 44.4).

Modifications to the Genomic RNA

The [+] strand RNA of each gene segment has a dimethylated cap-1 structure on its 5′ terminus,^{95,179,332} which is added by viral guanylyltransferase and methyltransferase activities present in the λ2 protein.^{106,295} The viral mRNA cap is recognized by translation initiation factor eIF4E^{61,346} and protects the free 5′ ends of the viral mRNA from 5′ exonucleases.¹⁷⁷ The 5′ terminus of the [−] strand RNA of each gene segment has an unblocked diphosphate.^{24,95} The terminal γ-phosphate of the [−] strand is removed by a phosphohydrolase activity (possibly mediated by the μ2 or λ1 protein) within reovirus particles.^{24,51,95,256} The 3′ end of each gene segment has an unblocked hydroxyl group.³³⁰ The viral [+] strand RNA does not contain a polyadenylate tract.

Sequence Features

Full-length sequences of the entire genomes of prototype mammalian orthoreovirus strains T1L, T2J, and T3D as well as those of several fusogenic orthoreovirus isolates have been determined (National Center for Biotechnology Information). The total length of the genome sequence is approximately 23,500 base pairs. The length of individual gene segments varies from 1,196 (T3D S4 gene segment) to 3,916 (T3D L2 gene

segment) nucleotides. Most homologous gene segments of different isolates display little (± 4 base pairs) or no variation in segment length. However, the S1 gene segment varies in length to a greater extent (1,463, 1,440, and 1,416 base pairs for the T1L, T2J, and T3D S1 gene segments, respectively).^{154,350}

Protein-Coding Strategies and Nomenclature

Twelve proteins are translated from the 10 T3D reovirus gene segments (Table 44.4). Eight of these segments encode a single protein, and two encode two proteins each. Eight of the 12 proteins are structural components of virions (λ1, λ2, λ3, μ1, μ2, σ1, σ2, and σ3), and four are nonstructural (μNS, μNSC, σ1s, and σNS). The nonstructural protein μNS was originally designated μ0.⁵⁵⁸ The assignment of individual proteins to specific gene segments was determined by analysis of viral reassortants^{344,345,390,518} and *in vitro* translation of viral mRNAs.³¹⁵

The names of the proteins encoded by each of the gene segments are designated by a Greek symbol that corresponds to large (λ), medium (μ), and small (σ) sizes, which are encoded by gene segments of the L, M, and S classes, respectively. For historical reasons, the numbering of gene segments does not always correspond to the numbering of the proteins (Table 44.4).

During reovirus infection, the [−] strand of each gene segment is transcribed to yield a full-length [+] strand RNA copy that is capped as it is released from the transcribing core particle. The viral mRNAs are not polyadenylated, but they are efficiently translated. ORFs of each gene segment are flanked by short nontranslated regions (NTRs). The AUG start codon for each gene segment is usually the first to be encountered by a scanning ribosome and, in most cases, it is found in an excellent context for translation initiation.²⁶⁹ The S1 gene segment encodes a second protein, σ1s, in an ORF overlapping that of the larger σ1 protein.^{160,241,429} The σ1s protein is translated from the first out-of-frame start codon within the σ1 ORF.³⁴³ Like the S1 gene segment, the M3 gene segment encodes a second protein, which is called μNSC. Translation of μNSC initiates from the second or third in-frame start codon of the

TABLE 44.4 Functions of Reovirus Proteins

Gene segment	Protein	Mass (Da)	Copy number per virion	Function
L1	$\lambda 3$	142,300	12	Minor inner-capsid protein; catalytic subunit of the viral RNA-dependent RNA polymerase; associates with nonstructural protein μ NS
L2	$\lambda 2$	144,000	60	Core spike protein; forms pentameric turret for insertion of attachment protein $\sigma 1$; associates with nonstructural protein μ NS; adds a 5' methylated cap to mRNAs
L3	$\lambda 1$	142,000	120	Major inner-capsid protein; associates with nonstructural protein μ NS; possible RNA helicase; may remove terminal phosphate from newly synthesized mRNA in preparation for capping
M1	$\mu 2$	83,300	24 ^a	Minor inner-capsid protein; probable RNA polymerase subunit; associates with nonstructural protein μ NS; stabilizes microtubules; nonspecific RNA-binding protein; may remove terminal phosphate from newly synthesized mRNA in preparation for capping; interferon antagonist
M2	$\mu 1$	76,300	600	Major outer-capsid protein; important for penetration of endosomal membrane by the viral core; probably regulates late mRNA synthesis from secondary transcriptase particles; influences efficiency of reovirus-induced apoptosis
M3	μ NS	80,000	NS ^b	Nonstructural replication protein; forms cytoplasmic inclusion structures; associates with nonstructural protein σ NS and core proteins $\lambda 1$, $\lambda 2$, $\lambda 3$, $\mu 2$, and $\sigma 2$; first viral protein found in association with viral mRNA
M3	μ NSC	75,000	NS	Nonstructural replication protein; function unknown; dispensable for replication in cell culture
S1	$\sigma 1$	49,200 (T3D) – 51,400 (T1L)	36	Attachment protein that binds to cell-surface glycans and junctional adhesion molecule A (JAM-A); determines virus serotype; determines cell and tissue tropism and route of virus spread in the host
S1	$\sigma 1s$	14,000	NS	Nonstructural replication protein; required for reovirus-induced cell-cycle arrest; required for reovirus hematogenous dissemination
S2	$\sigma 2$	47,200	150	Major inner-capsid protein; associates with nonstructural protein μ NS; binds weakly to dsRNA
S3	σ NS	41,000	NS	Nonstructural replication protein found early in viral inclusions; associates with nonstructural protein μ NS; nonspecific RNA-binding protein with high affinity for single-stranded RNA
S4	$\sigma 3$	41,500	600	Major outer-capsid protein; forms protective cap over $\mu 1$; nonspecific dsRNA-binding protein; influences efficiency of translation; associated with viral mRNA early in replication cycle; inhibits PKR activation

^aStoichiometry not known with certainty.

^bNS, nonstructural, not a component of viral particles.

m3 RNA.³¹⁶ There is no evidence that any reovirus protein is translated from a genomic [–] strand.

Terminal Nontranslated Regions

The reovirus gene segments contain short terminal NTRs (Fig. 44.4). The 5' NTRs range in length from 12 to 32 nucleotides, and their relative sizes may affect their translation efficiency.⁴⁰⁶ The 3' NTRs are a little longer and vary in length from 35 to 83 nucleotides. In general, NTR length of homologous gene segments is conserved between different virus isolates.³¹⁶

The [+] strand of all reovirus gene segments contains the 5' sequence GpCpUpA and the 3' sequence UpCpApUpC.¹⁴ Longer regions of sequence near the RNA termini and extending into the ORFs display less variability between isolates than sequences farther from the ends^{90,202,253} (Fig. 44.4). RNA-folding predictions suggest that sequences near the ends of the reovirus [+] strands can form panhandle structures, which may

be important for certain RNA functions.^{90,286,553} For example, the 5' and 3' NTRs include sequences and structural elements important for RNA packaging.^{405,408,409}

Genetics

Reassortment

Gene segment exchange (or reassortment) among reovirus strains occurs during mixed infections of cultured cells or animal hosts. The progeny of such mixed infections are commonly referred to as reassortant viruses. Many reovirus strains are distinguishable by signature electrophoretic profiles of their dsRNA gene segments in acrylamide gels (Fig. 44.3A). Co-infection of cells with such strains produces a collection of reassortant viruses in which the parental origin of each gene segment can be determined following electrophoresis of viral genomic dsRNA (Fig. 44.3B). Studies of reassortant viruses have been used to assign biological polymorphisms displayed

FIGURE 44.4. Reovirus gene segment coding strategies. The 10 reovirus gene segments demonstrate no significant sequence similarity except for the 5'-terminal four nucleotides ([+] 5'-GCUA-3') and 3'-terminal five nucleotides ([+] 5'-UCAUC-3'), which are invariant among all 10 segments. However, sizable regions of subterminal sequence are conserved among homologous gene segments across individual strains. Each of the reovirus gene segments is monocistronic with the exception of the M3 gene segment, which encodes μ NS and μ NSC in the same reading frame (μ NSC is an N-terminally truncated version of μ NS), and the S1 gene segment, which encodes σ 1 and σ 1s in overlapping reading frames. Nucleotide sequence conservation extends inward from both nontranslated regions (NTRs) into the gene-segment open reading frames and is maintained even at synonymous positions. Only the plus strand is shown here. Sequence ranges are based on strain type 3 Dearing and include the larger of the two reading frames in the S1 gene segment.

by different reovirus strains to specific viral gene segments. Thus, a phenotypic difference between two parental strains can be genetically mapped by screening the reassortant viruses in appropriate assays and correlating expression of the phenotype with a specific parental gene segment.

Reassortment of reovirus gene segments also occurs *in vivo*. Infection of mice perorally with strains T1L and T3D yields reassortant progeny in the stool and at sites of secondary replication.⁵²¹ In at least one case, a reassortant virus arising during such a mixed infection displays virulence properties that differ from both parental strains,⁴⁵¹ suggesting the selection of new mutations *in vivo*. Beyond experimental infection of animals, additional support for the hypothesis that reovirus gene segments reassort in nature is provided by analysis of nucleotide sequences of the L1,²⁷⁷ M1,⁵⁴¹ S1,¹³⁷ S2,⁹⁰ S3,²⁰² and S4²⁵³ gene segments derived from a panel of field-isolate strains isolated in the 1950s and 1960s by Leon Rosen.^{413,414,417} The topologies of phylogenetic trees constructed from protein-coding sequences of these gene segments are distinct, providing convincing evidence that these segments reassort in nature.

Reassortment is not entirely random. In a study of 83 reassortant viruses derived from strains T1L and T3D, statistically significant nonrandom associations of parental alleles were observed in the L1–L2, L1–M1, L1–S1, and L3–S1 gene segment pairs.³⁵² It is possible that these gene segments or their protein products cannot accommodate exchange with gene segments from another strain without the selection of fitness-compromising mutations. Additionally, the majority of progeny viruses resulting from mixed infections retains the genome constellation of the parental strains,¹⁶⁹ suggesting that viral replication is compartmentalized in some way.

Selection of Mutants: “Forward Genetics”

TEMPERATURE-SENSITIVE MUTANTS

Reovirus mutants with reduced capacity to replicate at elevated temperature, usually defined as 39°C or 40°C^{115,169,214} as opposed to 31°C, have been selected using a variety of conditions. Temperature-sensitive mutants mapping to seven of the 10 genetic groups (gene segments) of strain T3D were isolated after chemical mutagenesis with nitrous acid (groups B [L2], D [L1], and E [S3]), nitroso-guanidine (groups C [S2],

F [M3], and G [S4]), or proflavin (group A [M2]).^{169,233} Mutants from the other three groups were isolated from T3D stocks passaged serially at high multiplicity of infection (MOI) (group H [M1]) or from persistently infected cultures (groups I [L3] and J [S1]).^{5,6,8} The genetic groups were assigned to discrete gene segments by reassortant analyses or the capacity to complement temperature-sensitive mutants from other groups.^{344,387,390} Although the prototype isolates of groups F, H, and J have not been confirmed to be temperature-sensitive,¹¹³ a new strain for temperature-sensitive group H (M1 gene segment) has been isolated.¹¹³ Sequence analysis reveals coding changes in mutants from groups A,²¹⁴ C,⁵²⁷ E,⁵²⁶ G,¹²⁰ and H.¹¹³ Reversion of reovirus temperature-sensitive mutants has been documented to occur through a change at the site of the original mutation (true reversion)¹¹⁵ or as a consequence of a mutation in a second gene that suppresses the defect produced by the original mutation (extragenic suppression).^{389,391}

DELETION MUTANTS

Some reovirus isolates lose portions of their genomes during serial high-MOI passage.^{7,70,358,360,434} Deletions in the L1 and L3 gene segments occur most commonly, but L2 and M1 deletions also occur. Analysis of a series of internally deleted M1 gene segments indicates that the minimum sizes for retained 5'- and 3'-terminal regions of message-sense RNA are 132–135 and 182–185 bases, respectively,⁵⁵³ suggesting that these regions contain signals required for RNA synthesis or gene segment packaging. Differences in the capacity of strains T1L and T3D to accumulate deletions segregates with the L2 gene segment, while the M3 gene segment is a determinant of which viral gene segments incur deletions.⁷⁰ Functions of the L2 and M3 gene products λ 2 and μ NS, respectively, in synthesis or packaging of reovirus RNA may influence the generation or amplification of deletion mutations.

CELL-ADAPTED MUTANTS

Although usually cytolytic, reoviruses are capable of establishing persistent infections in many types of cells in culture.¹³⁶ These cultures are maintained by horizontal transmission of virus from cell to cell and can be cured of persistent infection by passage in the presence of reovirus-specific antibodies. During maintenance of L-cell cultures persistently infected with

reovirus, mutations are selected in both cells and viruses.^{4,139} Mutant cells selected during persistent infection have alterations in the expression of cathepsin L and do not support disassembly of wild-type virus.²² These cells in turn select mutant viruses (termed PI viruses) that have gained the capacity to bypass cellular blocks to infection by virtue of mutations in outer-capsid proteins $\sigma 1$ ⁵³² and $\sigma 3$,⁵²⁴ which promote more efficient disassembly. Studies of the virus-cell co-evolution that occurs during persistent reovirus infections have thus enhanced an understanding of reovirus entry (see Replication—Disassembly).

Nonsialic acid-binding reovirus strains have been adapted to growth in murine erythroleukemia (MEL) cells by serial passage.⁹¹ These variants have single amino-acid substitutions in the sialic acid-binding domain of $\sigma 1$ protein and have gained the capacity to bind sialylated glycans.⁹¹ Serial passage also has been used to select reovirus mutants for resistance to ammonium chloride,⁹⁹ which inhibits endosomal acidification, and E64,¹⁵⁷ which inhibits cysteine proteases. These mutants have alterations in $\sigma 3$ protein that enhance kinetics of viral disassembly. Other reovirus mutants have been selected during chronic infections of immunocompromised mice; these viruses are adapted to replicate more efficiently in the organs from which they were isolated.²⁰⁶

MUTANTS RESISTANT TO DENATURANTS

Treatment of reovirus with harsh denaturants (e.g., heat, extremes of pH, ethanol, phenol, or SDS) results in substantial losses in infectivity.¹⁴⁸ Strain-specific differences in susceptibility to inactivation by heat and ethanol have been mapped using reassortant viruses to the $\sigma 3$ -encoding S4 gene and $\mu 1$ -encoding M2 gene,¹⁴⁹ respectively. Concordantly, reovirus mutants selected for resistance to ethanol have mutations in the M2 gene.^{226,522} These mutants display increased thermostability and a decreased capacity to penetrate host-cell membranes.²²⁶

Directed Mutagenesis of the Genome: “Reverse Genetics”

The ability to engineer viruses that contain specific sequence modifications was first accomplished for mammalian reoviruses using a strategy involving message-sense RNA transcribed *in vitro* and a helper virus.⁴¹⁰ This system has been used to recover infectious particles containing gene segments derived from cloned DNA copies of single reovirus gene segments.^{405,407} Development of a plasmid-based reverse genetics system for members of the *Birnaviridae* family,⁵³⁹ which contain two genomic dsRNA segments, suggested that delivery of viral positive-strand RNA alone could launch successful production of viral progeny for a dsRNA virus. This approach proved possible with the development of an entirely plasmid-based reverse genetics system for reovirus in which viable viruses are generated from a set of 10 cloned cDNAs representing the complete viral genome²⁶¹ (Fig. 44.5). Gene segment cDNAs corresponding to strains T1L²⁶⁴ and T3D²⁶¹ were introduced into plasmids at sites flanked by the promoter sequence for T7 RNA polymerase and the hepatitis delta virus (HDV) ribozyme (Fig. 44.5A). Neither helper virus nor co-expression of viral replication proteins is required for recovery of infectious virus.

Reovirus can be recovered from cells in which T7 RNA polymerase is delivered transiently by infection with a recombinant vaccinia virus²³⁶ or from cells that constitutively express

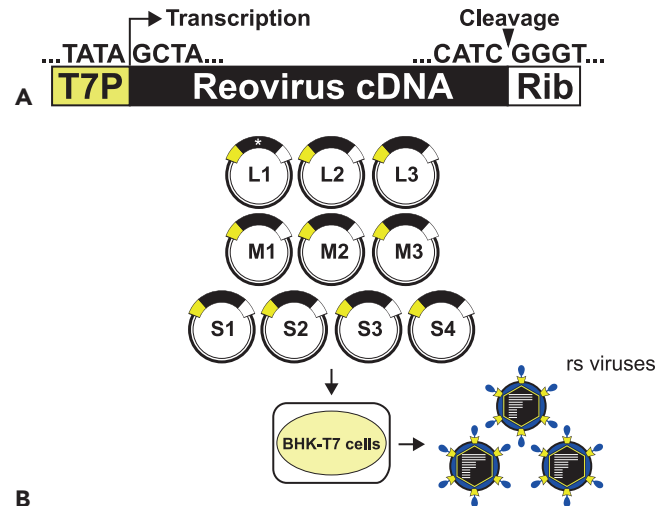

FIGURE 44.5. Recovery of reovirus from cDNA. **A:** Prototype reovirus gene segment cDNA in plasmid. Cloned cDNAs representing the 10 reovirus dsRNA gene segments are flanked by the bacteriophage T7 RNA polymerase promoter (T7P) and hepatitis delta virus ribozyme (Rib) sequences.

B: The 10 plasmid constructs are transfected into BHK cells expressing T7 RNA polymerase. Transcription within the cells generates the 10 different viral mRNAs, each with its authentic 5' end. Self-cleavage by the ribozyme generates authentic viral 3' ends. These mRNAs are translated and produce all 12 reovirus proteins, which can then direct a productive infectious cycle. Following 1 to 2 days of incubation, transfected cells are lysed by freeze-thaw, and viable virus is isolated by a plaque assay using L929 cells. An engineered silent substitution in one of the cloned cDNAs (indicated by an asterisk in the L1 gene segment) creates a unique molecular signature to confirm the plasmid origin of the recombinant strain (rs) viruses.

the enzyme⁷³ (Fig. 44.5B). Since T7 RNA polymerase initiates transcription at a defined guanosine residue³²⁹ and all reovirus RNAs contain the nucleotide sequence, GCUA, at the 5' terminus of the message-sense strand, T7 RNA polymerase produces transcripts with native reovirus 5' termini. Self-cleavage of the HDV ribozyme generates RNAs with native 3' termini.⁴⁰⁷ In cells transfected with plasmids encoding all 10 reovirus gene segments, viral gene products join with reovirus RNAs to form viral replication complexes, which mediate negative-strand synthesis and ultimately generate infectious particles. Inclusion of expression plasmids encoding reovirus proteins does not enhance recovery of recombinant reoviruses.⁵⁷ However, the efficiency of virus recovery is increased by using baby hamster kidney cells constitutively expressing T7 RNA polymerase⁷³ and reducing the plasmid number from 10 to four by combining reovirus gene segment cDNAs into multicistronic vectors.²⁶⁴

Plasmid-derived wild-type virus recapitulates properties of native virus in all cell-culture and *in vivo* models of reovirus infection studied to date.^{261,264} This reverse genetics approach has been used to introduce changes into the virion capsid and replication proteins to define the roles of individual amino acids, functional domains, and structural motifs in receptor utilization,^{259,395} virion disassembly,^{147,261} membrane penetration,^{121,123,430} replication biochemistry,³⁶⁹ inclusion

formation,^{239,263} interferon (IFN) expression,^{235,556} apoptosis induction,^{121,123} viral growth and spread *in vivo*,^{55,56,261} neurovirulence,^{121,123} and myocardial injury.²³⁵ The same strategy also can be exploited to engineer recombinant reoviruses for vaccine and oncolytic applications.

Genetic Complementation

A variety of complementation strategies have been developed to enable studies of viral mutations that would otherwise compromise viral viability. Stable expression in cultured cells of wild-type forms of temperature-sensitive mutant proteins allows replication of the corresponding temperature-sensitive mutant virus at nonpermissive temperature. This approach has been used to complement the replication of tsE (which segregates with the σ NS-encoding S3 gene segment) and tsH (which segregates with the μ 2-encoding M1 gene segment) by stable expression of the σ NS³³ and μ 2⁵⁵⁴ proteins, respectively. These complementing cell lines and temperature-sensitive mutant viruses could be used to define sequences in σ NS and μ 2 required for viral replication.

Recombinant reovirus outer-capsid proteins μ 1, σ 1, and σ 3 can bind and “recoat” purified subviral particles (ISVPs or cores) *in vitro* to generate infectious virion-like particles.^{83,84,244} These recoated particles have been used to identify sequences in μ 1, σ 1, and σ 3 proteins that function during cell entry and disassembly.^{81,84,243,531}

Reovirus replication is blocked in cell lines stably expressing small interfering RNAs (siRNAs) specific for reovirus transcripts.²⁶² RNAi-mediated inhibition of viral gene expression can be complemented by vectored expression of viral genes in which the siRNA target sequence has been altered to prevent siRNA-mediated degradation. This approach has been used to identify sequences in μ 2, μ NS, and σ NS proteins that function in viral inclusion formation and RNA synthesis.^{16,77,262,263} Limitations of this strategy include the efficiency of viral RNA knockdown and transfection efficiency of the complementation plasmids.

REPLICATION

Attachment

Reovirus Attachment Protein σ 1

The S1-encoded σ 1 protein (49–51 kDa, 455–470 aa) mediates viral binding to cellular receptors^{27,89,279,514} and influences target-cell selection in the infected host.^{28,515,517} It is a homotrimer present in 36 copies per virion.^{114,478} Structural information is available for the σ 1 protein of prototype type 3 strain, T3D. The 455 amino acids of T3D σ 1 fold into a filamentous trimer approximately 480 Å long and 90 Å wide at its broadest point, with a globular C-terminal head, a central body, and a slender N-terminal tail^{92,174,395} (Fig. 44.6A). Residues 310 to 455 comprise the head, which is constructed from two Greek-key motifs that assemble into an eight-stranded β -barrel.^{92,431} With the exception of the loop connecting β -strands D and E (D-E loop), which contains a 3_{10} helix, loops connecting individual strands of the β -barrel are very short. Residues 170 to 309 form the body domain, which is constructed primarily from repeating units of two antiparallel β -strands connected by short loops. Three such units assemble into a triple β -spiral, which is a motif observed to date only in viral fibers, including the

adenovirus fiber,⁵⁰⁵ bacteriophage PRD1 P5,³²¹ avian reovirus attachment protein σ C,²⁰³ and mammalian reovirus T3D σ 1.^{92,395} The body domain features four β -spiral repeats at the N-terminus (β 1– β 4, residues 170–235), a short α -helical coiled-coil (residues 236–251), and three additional β -spiral repeats (β 5– β 7, residues 252–309) at the C-terminus (Fig. 44.6A). The short α -helical coiled-coil corresponds to a narrowing in the body domain in a composite image of negative-stained electron micrographs of purified σ 1.¹⁷⁴ Residues 1 to 160 form the tail domain, the structure of which is unknown. However, a repeating heptad sequence motif suggests that this region forms an amphipathic α -helix, which likely assembles into an α -helical coiled-coil in the trimer.^{92,350} The extreme N-terminus of σ 1 does not contain any obvious sequence motifs. It is hydrophobic and anchors the protein into the pentameric turret formed by λ 2 in the reovirus virion.^{151,176,283} This symmetry mismatch (a trimer of σ 1 engaged to a pentamer of λ 2) suggests an interaction of limited strength, which may aid in σ 1 release during viral disassembly.⁴⁷²

The σ 1 molecule possesses discrete regions of flexibility^{92,174,395} (Fig. 44.6A, *arrows*). One site of substantial flexibility in T3D σ 1 is contributed by a four-residue insertion between the two most C-terminal β -spiral repeats (β 6 and β 7).^{78,92} Sequence alignments suggest that σ 1 of reovirus prototype strains T1L and T2J each contain a six-residue insertion at the same position.⁹² This insertion appears to correspond to a region of flexibility observed just below the σ 1 head in electron micrographic images.¹⁷⁴ A second region of flexibility is observed at the midpoint of σ 1 and corresponds to the transition between the predicted α -helical coiled-coil region of the tail and the β -spiral-containing body. A final region of flexibility close to the N-terminus likely represents the virion insertion domain.^{92,174,350}

Glycan Binding by σ 1

Reoviruses display the capacity to agglutinate erythrocytes of several mammalian species.²⁸⁴ For type 3 reoviruses, hemagglutination is mediated by interactions of the σ 1 protein with terminal α -linked sialic acid residues on several glycosylated erythrocyte proteins such as glycophorin A.^{183,376} Strain T3D exhibits a reduced capacity to agglutinate erythrocytes following treatment with neuraminidase, which removes terminal sialic acid moieties.¹⁸³ Preincubation of L cells with neuraminidase or virus with sialosides also significantly diminishes T3D binding.^{184,375} Sialic acid residues linked in α 2,3 or α 2,6 configurations effectively block type 3 reovirus binding to L cells.³⁷⁵ Reovirus T3D binds to sialoglycophorin, but not to asialoglycophorin, with an avidity of approximately 5×10^{-9} M,²⁶ which is a property mediated by the σ 1 protein.⁸⁹

Binding to sialic acid is essential for reovirus infection of some types of cultured cells, such as MEL cells.^{91,422} Sequence polymorphisms within the σ 1 body domain at residues 198, 202, and 204 determine the capacity of field-isolate reovirus strains to bind sialic acid and infect MEL cells.^{138,421} Furthermore, nonsialic acid-binding type 3 variants can be adapted to growth in MEL cells during serial passage. These variants have gained the capacity to bind sialic acid and contain sequence changes within the polymorphic region of the σ 1 body. In addition, sialic acid binding also serves an important role in reovirus tropism and pathogenesis *in vivo*. A sialic acid-binding strain of reovirus, but not a nonsialic acid-binding strain, causes bile

FIGURE 44.6. Structure of reovirus $\sigma 1$ in complex with its receptors sialic acid and junctional adhesion molecule-A.

A: Full-length model of $\sigma 1$. A full-length depiction of $\sigma 1$ was generated by modeling a predicted trimeric α -helical coiled coil and linking it to the N-terminus of the largest crystallized fragment of $\sigma 1$ (residues 170–455 of strain type 3 Dearing [T3D] $\sigma 1$).³⁹⁵ The three monomers of the crystallized fragment are shown in *blue*, *red*, and *yellow*; the model is shown in *grey*. Tail, body, and head regions are indicated. Regions of flexibility are marked by *arrows*. A sequence polymorphism that confers susceptibility to cleavage by intestinal proteases is indicated with an *asterisk*. The approximate locations of binding sites for sialic acid and junctional adhesion molecule-A (JAM-A) are shown. Amino (N)- and carboxy (C)-termini are indicated. **B:** The T3D $\sigma 1$ protein in complex with α -2,3-sialyllactose.³⁹⁵ Residues in the binding region are drawn in *stick representation*, while the remainder of the protein is shown as a *ribbon drawing*. The side chain of Asn189 (*blue*) is contributed by a neighboring $\sigma 1$ monomer. The α -2,3-sialyllactose is shown in *stick representation*, with carbons in *orange*, oxygens in *red*, and nitrogens in *blue*. The sugar moieties are labeled Sia (sialic acid), Gal (galactose), and Glc (glucose). Bridging waters are shown as *orange spheres*. Hydrogen bonds and salt bridges are represented with *broken lines*. **C:** The T3D $\sigma 1$ protein in complex with JAM-A. *Ribbon drawing* of a complex formed between the trimeric $\sigma 1$ head domain and monomeric JAM-A D1, viewed perpendicular to the threefold symmetry axis.²⁵⁹ Beta-strands C, C', F, and G of JAM-A D1 are indicated on the right. Many of the residues in $\sigma 1$ that engage JAM-A reside in the loop that connects β -strands D and E and its 3_{10} helix.

duct injury in newborn mice and exhibits 1,000-fold greater binding capacity for human cholangiocarcinoma cells²⁸ (see Pathogenesis and Immunity—Hepatobiliary System).

The structure of a T3D $\sigma 1$ construct encompassing the body and head domains in complex with α -2,3-sialyllactose has been determined.³⁹⁵ The oligosaccharide binds in a shallow groove next to the loop connecting the second and third β -spiral repeats ($\beta 2$ and $\beta 3$). The $\sigma 1$ protein contains three identical binding sites, one on each chain, and all three are occupied by α -2,3-sialyllactose molecules in the crystal structure, with the sialic acid making identical and extensive contacts in each chain (Fig. 44.6B). Remarkably, $\sigma 1$ also can form complexes with α -2,6-sialyllactose and α -2,8-di-sialyllactose.³⁹⁵ In each case, the terminal sialic acid forms almost all of the contacts with $\sigma 1$ in an identical manner, while the remaining compo-

nents of the oligosaccharides make little or no contacts. Studies using point-mutant viruses indicate that Asn198, Arg202, Leu203, Pro204, and Gly205 are required for hemagglutination and infection of MEL cells,³⁹⁵ suggesting that these residues serve a functional role in T3D $\sigma 1$ –sialic acid interactions.

Type 1 reoviruses also appear to bind sialic acid in some contexts. T1L, but not T3D, binds the apical surface of microfold (M) cells, but not enterocytes, in tissue sections of rabbit Peyer patches.²¹⁷ Binding is inhibited by preincubation of the tissue sections with neuraminidase or with lectins that specifically recognize α -2-3-linked sialic acid. The capacity of T1L to bind the apical surface of M cells segregates with the S1 gene segment using reassortant genetics and with reovirus particles recoated with recombinant $\sigma 1$ protein. The interaction between T1L $\sigma 1$ and sialic acid is especially intriguing as type 1 reoviruses are

incapable of infecting MEL cells, a property dependent on sialic acid binding that segregates with the S1 gene segment,⁴²² and are insensitive to the growth-inhibitory effects of neuraminidase treatment of L cells.³⁴⁹ These findings suggest that the functional glycans engaged by types 1 and 3 reoviruses differ, even though such glycans appear to terminate in α -2,3-linked sialic acid. Concordantly, studies using expressed protein suggest that T1L engages carbohydrates using a domain that differs from that used by T3D to bind carbohydrates.⁸⁹

Type 2 reoviruses also are capable of producing hemagglutination,²⁸⁴ but little is known about the basis for this property.

JAM-A Binding by σ 1

Reovirus strains of all three serotypes use junctional adhesion molecule-A (JAM-A, also known as F11R/JAM/JAM1), a member of the immunoglobulin superfamily,^{27,309,529} as a receptor.^{27,76,382} JAM-A was identified as a reovirus receptor using a genetic screen and subsequently shown to bind directly to the σ 1 head domain with nanomolar affinity.^{27,431} Human and murine homologs of JAM-A, but not JAM family members JAM-B or JAM-C, serve as receptors for all reovirus serotypes and strains tested to date.^{27,76,382} The role of JAM-A as a reovirus receptor *in vivo* has been examined using JAM-A-null mice¹³ (see Pathogenesis and Immunity – Spread of Virus). Following peroral inoculation, JAM-A is dispensable for reovirus growth in the intestine. However, it is required for infection of vascular endothelial cells and promotes efficient hematogenous dissemination of reovirus to sites of secondary infection. Thus, JAM-A serves as a high-affinity reovirus receptor in cultured cells and *in vivo*. Receptors for reovirus at other sites within the host, including the central nervous system (CNS), have not been conclusively identified.

Structural and biochemical studies highlight the regions and specific interactions that mediate reovirus engagement of JAM-A.^{76,92,173,204,259,382} (Fig. 44.6C). The largest area of conserved residues in σ 1 forms the D-E and F-G loops in the head domain.^{76,92} The crystal structure of the σ 1 head domain in complex with the JAM-A D1 domain reveals that residues in this region, centered at the D-E loop and its 3_{10} helix, form the largest area of JAM-A contact.²⁵⁹ Interactions in this area are polar and involve residues Thr380, Gly381, and Asp382. A second area of JAM-A contact includes residues within the σ 1 body, just N-terminal to the head domain. Interactions in this region are largely hydrophobic and involve Arg316 in β -strand A of the head, β -spiral residues Arg297 and Tyr298, the α -helical turn that connects the β -spiral with the β -barrel, and Pro377.

The D1 domain of JAM-A is required for high-affinity binding to σ 1.^{173,204,382} Mutation of individual JAM-A D1 domain residues Arg59, Glu61, Lys63, Leu72, Tyr75, and Asn76 that lie in or adjacent to the dimer interface diminishes or abolishes σ 1 binding and reovirus infectivity.²⁰⁴ Concordantly, the structure of the σ 1–JAM-A complex shows that each σ 1 trimer binds three independent JAM-A monomers. Contacts primarily involve the JAM-A dimer interface and a conserved region at the base of the σ 1 head^{92,259} (Fig. 44.6C). In addition, the structure of the σ 1–JAM-A complex also identifies residues bound by σ 1 that are found just outside the dimer interface of JAM-A.²⁵⁹ These residues may serve as initial contact points for σ 1 and facilitate disruption of the JAM-A homodimer to allow interaction of σ 1 with the JAM-A dimer

interface. It is also possible that a cavity in the JAM-A dimer interface renders the homodimer intrinsically unstable, thereby promoting its disruption by σ 1. Regardless of the mechanism, the σ 1–JAM-A interaction is thermodynamically favored, as the K_D is $\sim 1,000$ -fold lower than the K_D of the JAM-A homodimer interaction.^{204,259,506}

The presence of discrete receptor-binding domains in σ 1 suggests that reoviruses employ a multiple-step binding process similar to that used by some herpesviruses^{109,465} and retroviruses.^{46,503} Binding studies using isogenic point-mutant viruses T3SA+ and T3SA–, which vary only in the capacity to engage sialic acid,²⁶ support this hypothesis. Kinetic analyses using inhibitors of sialic acid and JAM-A binding demonstrate that sialic acid is engaged first in the adsorption process, as the inhibitory effect of sialic acid analogs on infection by T3SA+ occurs at early but not late time points.²⁶ However, a σ 1-specific monoclonal antibody that blocks virus binding to JAM-A inhibits viral infectivity at both early and late times during adsorption.²⁶ Thus, reovirus binding to sialic acid enhances virus attachment through rapid adhesion of virus to the cell surface where access to JAM-A is thermodynamically favored. It is not known whether binding to sialic acid induces structural changes in σ 1 that affect its capacity to interact with JAM-A. However, it is clear that sialic acid binding is not a necessary prerequisite for JAM-A binding, as reoviruses incapable of binding sialic acid are capable of binding JAM-A.²⁷ It is possible that engagement of JAM-A by the σ 1 head leads to conformational changes in other regions of σ 1 or in other capsid components.¹⁶⁸

Cleavage of σ 1 by Intestinal Proteases

Treatment of virions of some reovirus strains with intestinal proteases *in vitro* to generate ISVPs leads to cleavage of the σ 1 protein.^{87,349} Strain-specific differences in cleavage susceptibility segregate with a single amino acid polymorphism in the short α -helical coiled-coil in the body domain of σ 1 (Fig. 44.6A, asterisk). Strains like T3D with a threonine at position 249 in σ 1 are susceptible to cleavage by trypsin after Arg245, whereas those with an isoleucine at position 249 are resistant to cleavage.⁸⁷ It is possible that Thr249 disrupts the α -helical coiled-coil and allows access to sites that otherwise would be shielded from protease.^{87,349} Conversion of T3D virions to ISVPs by intestinal proteases leads to loss of the σ 1 head domain and a resultant 90% reduction in infectivity.³⁴⁹ Since cleavage of σ 1 occurs C-terminal to the sialic acid-binding pocket, residual infectivity of T3D ISVPs is dependent on this carbohydrate.³⁴⁹ Susceptibility of the T3D σ 1 protein to cleavage likely accounts for the attenuated virulence of this strain after oral inoculation.^{53,254,419}

Determinant of Neutralizing Antibody Responses

In addition to its function in receptor engagement, the σ 1 protein is the target of serotype-specific neutralizing antibodies.^{75,469,516} For example, serotype-specific monoclonal antibodies 5C6⁵⁰⁸ and 9BG5⁷⁵ neutralize infectivity of type 1 and type 3 reovirus strains, respectively, and bind the σ 1 head domain in a serotype-specific fashion.⁸⁹ Variants of T1L selected for resistance to neutralizing monoclonal antibodies have mutations at Ala415, Gln417, Asn445, and Gly447,²¹⁶ which are located in the σ 1 head. Similarly, variants of T3D selected for resistance to neutralizing monoclonal antibodies have mutations at

Asp340 and Glu419,³⁰ which are also located in the $\sigma 1$ head. Interestingly, for both T1L and T3D, the sites in $\sigma 1$ altered in the neutralization-resistant variants are in close proximity on adjacent monomers,^{92,216} suggesting an epitope that spans two monomers in the $\sigma 1$ trimer. Neutralization-resistant variants of T3D display diminished neurovirulence and altered CNS tropism in mice,^{467,468} perhaps as a consequence of altered $\sigma 1$ receptor recognition in the murine CNS.

Entry

Internalization by Clathrin-Dependent Endocytosis

Following attachment to cell-surface glycans and JAM-A, reovirus is internalized by receptor-mediated endocytosis (Fig. 44.7). Thin-section electron micrographs show virions in structures

that appear to be clathrin-coated pits on the cell surface and in clathrin-coated vesicles in the cytoplasm,^{59,60,298,421,480} suggesting clathrin-dependent uptake. This finding was confirmed using video fluorescence microscopy in which reovirus virions and clathrin are observed to colocalize during internalization.¹⁵⁸ Treatment of cells with chlorpromazine, which impairs clathrin-mediated endocytosis, inhibits reovirus internalization and infection,²⁹⁸ suggesting a functional role for clathrin in reovirus entry. However, there is mounting evidence that both clathrin- and caveolin-dependent mechanisms can be employed by some viruses to enter host cells.^{275,385} Although there are no published reports of clathrin-independent uptake strategies for reovirus, a role for caveolae or other entry mechanisms in reovirus cell entry has not been conclusively excluded.

FIGURE 44.7. Schematic of reovirus cell entry and disassembly. Following attachment to (1) cell-surface carbohydrate (α -linked sialic acid for serotype 3 reoviruses) and (2) junctional adhesion molecule-A (JAM-A), (3 and 4) virions enter cells by receptor-mediated endocytosis using a mechanism that requires $\beta 1$ integrin. Following endocytic uptake (5), activation of Src is required for (6) correct trafficking of virions to an endocytic compartment where the viral outer-capsid undergoes acid-dependent proteolysis. The first disassembly intermediate is the infectious subviral particle (ISVP), which is characterized by loss of $\sigma 3$ and cleavage of $\mu 1C$ into particle-associated fragments δ and ϕ . The ISVP then undergoes further conformational changes (7) to form the ISVP*. The ISVP* is characterized by conformational rearrangements of the $\mu 1$ fragments to expose hydrophobic residues, release of $\mu 1N$ and ϕ , and loss of attachment protein $\sigma 1$. The $\mu 1$ cleavage fragments mediate penetration (8) through the endosomal membrane releasing the transcriptionally active core (9) into the cytoplasm. The cellular chaperone protein Hsc70 participates in the membrane penetration process.

Regardless of the internalization mechanism, reovirus particles are sorted into vacuoles resembling endosomes and lysosomes during the entry process.^{59,60,158,298,421,480}

β 1 Integrins Promote Entry and Sorting in the Endocytic Compartment

Expression of a JAM-A truncation mutant lacking a cytoplasmic tail allows reovirus to infect nonpermissive cells,²⁹⁷ suggesting that molecules other than JAM-A mobilize the internalization apparatus that promotes reovirus cell entry. The L2-encoded λ 2 protein (144 kDa, 1288–1289 aa) contains conserved integrin-binding motifs, RGD and KGE,^{64,438} suggesting that reovirus employs integrin-dependent internalization mechanisms to enter cells. The RGD and KGE sequences are displayed on surface-exposed loops of λ 2,³⁹⁴ where they could interact with integrins to promote internalization. However, direct interactions between λ 2 and integrins have not been reported. Interestingly, the L2 gene segment is genetically linked to viral shedding in infected mice and spread to littermates,²⁵⁴ suggesting a role for λ 2 in reovirus-induced disease.

Treatment of cells with antibodies specific for β 1 integrin reduces reovirus infection, while antibodies specific for other integrin subunits expressed on permissive cells, including those specific for α integrin subunits, have no effect.²⁹⁷ However, antibodies specific for β 1 integrin do not alter infection by *in vitro*-generated ISVPs,²⁹⁷ which directly penetrate the plasma membrane and do not require endocytosis.^{226,294} Concordantly, β 1 integrin-specific antibodies do not alter the binding of reovirus to JAM-A.²⁹⁷ These findings suggest that β 1 integrin blockade inhibits endocytic uptake of virions following JAM-A engagement. In comparison to β 1 integrin-expressing cells, β 1-null cells are substantially less susceptible to infection by reovirus virions, while infection by ISVPs is equivalent in both cell types.²⁹⁷ Diminished reovirus replication in β 1-null cells correlates with diminished viral uptake, indicating that β 1 integrin is required for efficient reovirus cell entry.

NPXY motifs in the β 1 integrin cytoplasmic tail play a key role in sorting reovirus within the endocytic compartment. NPXY motifs are found in the cytoplasmic domains of many receptors^{94,125,367} and recruit adaptor protein 2 or disabled protein 2^{341,367} to initiate clathrin assembly at the plasma membrane. Substitution of a tyrosine with a phenylalanine residue in either or both β 1 integrin NPXY motifs (NPXF) results in inefficient internalization of reovirus virions and diminished infectivity.²⁹⁸ Infection of cells expressing NPXF β 1 integrin results in distribution of virions to lysosomes where they are degraded, suggesting that the β 1 integrin NPXY motifs target reovirus to the precise endocytic organelle that permits functional disassembly.

Src Kinase Regulates Endosomal Sorting of Reovirus

The Src family of kinases contains eight members, Blk, Fgr, Fyn, Hck, Lck, Lyn, Src, and Yes, three of which—Fyn, Src, and Yes—are expressed in most cell types.⁴⁹¹ Src-family kinases regulate numerous cellular processes including proliferation, differentiation, migration, adhesion, and cytoskeletal rearrangements⁴⁹¹ and transduce signals from a variety of receptors.^{145,182,308,427} In a small-molecule inhibitor screen, genistein, a broad-spectrum

tyrosine-kinase inhibitor, and PP2, a specific Src-family-kinase inhibitor, were found to diminish reovirus infectivity by inhibiting an early step in the viral life cycle.²⁹⁹ Although neither inhibitor impedes internalization of reovirus virions, both inhibitors target virions to lysosomes. At early times following infection, Src co-localizes with reovirus virions and is phosphorylated at the activation residue, Tyr416, suggesting that reovirus induces activation of Src during entry and traffics with Src during sorting in the endocytic compartment. Reduction of Src expression by RNAi decreases reovirus infectivity.²⁹⁹ These findings suggest that Src is part of a signaling network that targets reovirus to endocytic organelles for viral disassembly and thus promotes functional entry into host cells. The precise mechanism by which Src mediates these effects is unknown.

Disassembly

Cleavage of σ 3: The First Step in the Reovirus Disassembly Cascade

In cellular endosomes, reovirus virions undergo stepwise disassembly to form discrete intermediates, the first of which is the ISVP^{21,60,85,456,480} (Fig. 44.7). ISVPs are characterized by the loss of σ 3, a conformational change in σ 1, and cleavage of μ 1 to form δ and ϕ . The rate-limiting step in reovirus disassembly is the proteolytic removal of the S4-encoded σ 3 protein (41 kDa, 365 aa).^{21,480} In some cell types, proteolysis of σ 3 is dependent on acidic pH^{139,480} and endocytic cysteine proteases.²¹ Murine L929 fibroblast cells treated with inhibitors of endosomal acidification, such as ammonium chloride⁴⁸⁰ or bafilomycin A1,³¹⁰ or inhibitors of cysteine proteases, such as E64,²¹ do not support reovirus replication when infection is initiated by virions but do so when infection is initiated by ISVPs. Thus, the block to reovirus replication imposed by these inhibitors in murine L929 cells occurs following internalization but prior to disassembly, which is coincident with the proteolysis of σ 3.

Cathepsins B and L, which reside in late endosomes and lysosomes,⁸⁶ catalyze reovirus disassembly in fibroblasts.¹⁵⁶ Both enzymes are optimally active at acidic pH and serve functions in extracellular matrix formation, antigen presentation, and apoptosis.⁸⁶ These enzymes also mediate cell entry of several other viruses, including Ebola virus⁸² and SARS coronavirus.²²⁹ Cathepsin S, an acid-independent cysteine protease required for processing internalized antigens,⁴⁰¹ and the acid-independent serine protease neutrophil elastase can mediate uncoating of some reovirus strains in monocyte and macrophage cell lines.^{191,193} It is possible that the broad tissue tropism displayed by reovirus is determined in part by the multiple host proteases capable of mediating its disassembly.²⁴⁷

Proteolytic enzymes also are required for reovirus infection following peroral inoculation of mice^{29,54} (see Pathogenesis and Immunity—Entry into the Host). Reovirus virions are converted to ISVPs in the intestinal lumen by the resident serine proteases chymotrypsin and trypsin. ISVPs produced in this fashion enter intestinal M cells to allow systemic dissemination of reovirus in the host.¹² ISVPs generated by chymotrypsin or trypsin *in vitro* or in the gut lumen^{29,54} display a protein profile (loss of σ 3 and cleavage of μ 1) indistinguishable from that of ISVPs generated in the endocytic compartment of cells.^{22,156}

Sequences in σ 3 that influence its susceptibility to proteolysis have been identified through studies of viruses selected

FIGURE 44.8. Structure of reovirus $\sigma 3$ with cleavage sites. **A:** The amino acid sequence of $\sigma 3$ from amino acids 241 to 255 is shown. Arrows highlight cathepsin L cleavage sites identified by N-terminal sequencing of $\sigma 3$ cleavage products following treatment of reovirus strain type 1 Lang (T1L) with cathepsin L *in vitro*. **B:** Cathepsin L cleavage sites are highlighted in the crystal structure of $\sigma 3$. A ribbon diagram of the crystal structure of type 3 Dearing $\sigma 3$ ³⁶⁸ is displayed on the left. The cathepsin L cleavage sites in T1L are depicted in *blue* between amino acids 243 and 244 and between 250 and 251. Surrounding residues, from amino acids 241 to 253, are shown in *yellow*. The C-terminal residues of $\sigma 3$, from amino acids 340 to 365, are in *red*. Amino acid 354, which is altered in a variety of mutant viruses selected for accelerated disassembly kinetics, is in *green*. The virion-distal end of $\sigma 3$ is at the top of the figure, and the virion-proximal end and N-terminus are at the bottom. **C:** An enlarged view of the boxed region of $\sigma 3$ indicated in **B** is shown using the same color scheme. Side chains of amino acids 243, 244, 250, 251, and 354 are depicted in *stick representation*.

during persistent infection (PI viruses) or mutant viruses selected for resistance to either cysteine protease inhibitor E64 (D-EA viruses)¹⁵⁷ or ammonium chloride (ACA-D viruses).⁹⁹ These viruses exhibit accelerated kinetics of disassembly and harbor a tyrosine-to-histidine mutation at amino acid 354 (Y354H) near the C-terminus of the protein^{99,157,524} (Fig. 44.8). Cryo-EM image analysis of a PI virus with an isolated Y354H mutation reveals a structural alteration in $\sigma 3$ at a hinge region located between its two major domains.⁵³¹ These findings suggest that the C-terminus of $\sigma 3$ influences susceptibility of the protein to cleavage. Interestingly, the $\sigma 3$ amino acid sequence of strain T3A differs from that of T3D at eight positions, including Y354H. However, a glycine-to-glutamate substitution at position 198 in T3A $\sigma 3$ suppresses the disassembly-enhancing effects of His354,¹⁴⁷ suggesting the existence of an allosteric network regulating $\sigma 3$ cleavage.

The $\sigma 3$ C-terminus also dictates strain-specific differences in the susceptibility of $\sigma 3$ to proteolytic attack.^{243,244} The $\sigma 3$ protein of strain T1L is cleaved more rapidly than that of T3D. Analysis of ISVPs recoated with chimeric $\sigma 3$ proteins generated from T1L and T3D revealed that the C-terminus is primarily responsible for the rate of $\sigma 3$ proteolysis. Moreover, sequence polymorphisms at residues 344, 347, and 353 in $\sigma 3$ contribute to this effect.²⁴³

Treatment of reovirus virions *in vitro* with either cathepsin B or cathepsin L leads to an initial cleavage of $\sigma 3$ at a terminus.¹⁵⁶ Since sequence polymorphisms in the $\sigma 3$ C-terminus

determine susceptibility to proteolysis, the initial cleavage of $\sigma 3$ probably occurs in this region. During proteolysis by cathepsin L, subsequent cleavages occur between residues 243 to 244 and 250 to 251¹⁵⁶ (Fig. 44.8A). These cleavage sites are physically located near the C-terminus in the $\sigma 3$ crystal structure³⁶⁸ (Fig. 44.8B and C). Because of this proximity, the small end fragment released following initial cathepsin L cleavage likely exposes the cleavage sites between residues 243 to 244 and 250 to 251, rendering them sensitive to proteolysis. The C-terminus therefore appears to control access to internal, proteolytically sensitive sites in $\sigma 3$. Because reovirus disassembly in some cell types is acid-dependent,^{139,480} the C-terminus might be primed for movement at acidic pH. Mutations near the C-terminus, like Y354H, may alter the conformation of the protein to allow improved access to these cleavage sites and thus accelerate outer capsid disassembly.⁵³¹

Conformational Changes in $\sigma 1$

The disassembly of reovirus virions to ISVPs is accompanied by a dramatic conformational change in $\sigma 1$. Electron micrographs of negatively stained reovirus virions and ISVPs reveal filamentous projections extending up to 400 Å from the surface of ISVPs but not virions.¹⁷⁶ These images suggest that $\sigma 1$ adopts a compact form in the virion and a more extended one in the ISVP. Cryo-EM image reconstructions of virions and cores lack a discernable density corresponding to $\sigma 1$ at the icosahedral vertices^{151,323} (Fig. 44.2). However, cryo-EM image analysis of

ISVPs demonstrates discontinuous density for $\sigma 1$ extending ~ 100 Å from each vertex (Fig. 44.2). Presumably, the full length of $\sigma 1$ is not visible in reovirus particles because the molecule is flexible and icosahedral averaging was employed for the cryo-EM image reconstructions. As further evidence of the conformational alterations in $\sigma 1$ during viral disassembly, proteolytic cleavage of T3D $\sigma 1$ during virion-to-ISVP conversion increases viral hemagglutination capacity,³⁴⁹ suggesting enhanced access to the sialic acid-binding region as a consequence of extension of the $\sigma 1$ tail and body domains. Interdomain regions of flexibility in $\sigma 1$ ¹⁷⁴ (Fig. 44.6) may be required to allow such conformational rearrangements.

Electron micrographs of purified $\sigma 1$ show molecules with either single- or multilobed head domains,¹⁷⁴ suggesting another type of structural alteration in $\sigma 1$ in which the head can exist in both “open” and “closed” conformations. Although neither the mechanism nor the functional significance of this $\sigma 1$ conformational change is understood, structural studies of $\sigma 1$ provide clues about how this change might occur. A cluster of six conserved aspartic acid residues on a rigid β -hairpin at the base of the $\sigma 1$ head, sandwiched between hydrophobic residues that block access to solvent, forms the main contact area between monomers in the trimer.^{92,431} Of the two aspartic acid residues contributed by each monomer, one (Asp346) is neutralized by a salt-bridge interaction with a nearby residue, while the other (Asp345) is not.^{92,431} The three Asp345 side chains closely appose each other at the center of the trimer in an otherwise hydrophobic environment. Since accumulation of negative charge in this region is predicted to destabilize the trimer,⁷⁸ and an aspartate-to-asparagine mutation results in $\sigma 1$ trimers with a structure indistinguishable from wild-type,⁴³¹ it is likely that Asp345 is protonated in the $\sigma 1$ crystal structure,⁹² thus representing the “closed” conformation of $\sigma 1$. This conformation might form during crystallization at near-neutral pH and physiologically in conditions of low pH, similar to those encountered in the endocytic compartment during reovirus entry.⁴³¹ Thus, the aspartic acid sandwich motif may contribute to $\sigma 1$ conformational rearrangements by acting as a molecular switch that

mediates the oligomeric state of the $\sigma 1$ head, depending on environmental pH.⁴³¹

Membrane Penetration

Critical Function of the $\mu 1$ Protein

Studies to assess the capacity of reovirus entry intermediates to penetrate artificial lipid bilayers, model membranes of erythrocytes, or membranes of cells that support reovirus infection indicate that ISVPs but not virions or cores mediate membrane penetration.^{59,80,83,84,226,294,492} Such studies led to the idea that ISVPs or related subviral particles are the membrane-active intermediates in the reovirus entry pathway. Since ISVPs differ from cores by the presence of outer-capsid proteins $\sigma 1$ and $\mu 1$,^{114,151} and because cores recoated with $\mu 1$ and $\sigma 3$ *in vitro* and then treated with chymotrypsin to remove $\sigma 3$ are capable of membrane penetration,⁸³ these findings point to a role for the M2-encoded $\mu 1$ protein (76 kDa, 708 aa) in membrane penetration. This biochemical evidence also is supported by several genetic studies. Differences in membrane-penetration efficiency displayed by reovirus strains T1L and T3D segregate with the M2 gene segment.^{79,294,430} Additionally, viruses selected for resistance to denaturants such as ethanol contain mutations within the M2 gene segment and display alterations in membrane penetration capacity.^{79,123,226,522} Together, these data demonstrate a function for the $\mu 1$ protein in membrane penetration.

The $\mu 1$ protein is N-terminally myristoylated³⁵⁴ and folds into four distinct domains²⁸⁹ (Fig. 44.9). Domains I, II, and III are primarily α -helical and serve as the base of the protein. Domain IV forms a jelly-roll β -barrel commonly found in the capsid proteins of many nonenveloped viruses.²¹¹ This domain extends distally and interacts extensively with similar domains of the neighboring $\mu 1$ molecules and with $\sigma 3$. The $\mu 1$ protein also contains three proteolytic cleavage sites (Fig. 44.9B). These include an autocatalytic cleavage site at amino acid 42, which separates $\mu 1N$ and $\mu 1C$, a cleavage site at approximately amino acid 580, which releases the δ and ϕ fragments, and a cleavage site at the C-terminus that releases a ~ 10 amino acid peptide.^{81,320,351,366} While the physiologic roles of both the δ - ϕ and the C-terminal cleavages are unclear, studies using reovirus

FIGURE 44.9. Structure of reovirus $\mu 1$ with cleavage sites. A: Ribbon diagram of the crystal structure of the $\mu 1$ - $\sigma 3$ heterohexamer from strain type 1 Lang (T1L).²⁸⁹ The $\mu 1$ monomers are in blue, red, and yellow; the $\sigma 3$ monomers are in grey. **B:** Cleavage products of the $\mu 1$ protein. (The C-terminal cleavage is not depicted.) **C:** Ribbon diagram of the crystal structure of the T1L $\mu 1$ monomer showing regions corresponding to the cleavage products. The domain color code is as depicted in B.

cores recoated with a $\mu 1N$ - $\mu 1C$ cleavage-resistant $\mu 1$ mutant indicate that cleavage of $\mu 1$ to generate $\mu 1N$ and $\mu 1C$ is required for membrane penetration and virion infectivity.³⁶⁶ Since $\mu 1N$ is released from viral particles, it is postulated that cleavage of $\mu 1$ is required for release of $\mu 1N$, which then interacts with membranes as a function of its myristoyl moiety to effect membrane penetration.²³⁸

Formation of the ISVP*

In the native $\mu 1$ structure present in virions and ISVPs, the myristoylated $\mu 1N$ fragment is buried inside a hydrophobic cavity in the α -helical pedestal formed by portions of domains I, II, and III.^{289,549} Based on this observation, massive conformational rearrangements resulting in unwinding of the $\mu 1$ trimer must be required to release $\mu 1N$ during cell entry.^{289,547} Evidence for conformational changes in particle-associated $\mu 1$ following interaction of ISVPs with membranes or when exposed to high salt concentrations has led to the identification of an ISVP-like entry intermediate in the reovirus cell entry pathway.⁷⁹ This intermediate, referred to as the ISVP*, is characterized by changes in the conformation of the $\mu 1$ δ fragment, loss of the $\sigma 1$ protein, and an increase in the overall hydrophobicity of the particle.⁷⁹ The autocatalytic cleavage of $\mu 1$ to form $\mu 1N$ and $\mu 1C$ also occurs in part during ISVP* formation.³⁵³ Thus, the $\mu 1$ protein associated with ISVPs is in a metastable state primed to undergo conformational changes and autocatalytic cleavage to assume a more hydrophobic structure capable of interaction with membranes. While it is not understood how these conformational changes in $\mu 1$ are triggered, it is thought that interaction of an anion-binding site in domain IV with phospholipid head groups in endosomal membranes might trigger the requisite rearrangements in $\mu 1$ that reveal the myristoylated $\mu 1N$ and the internal hydrophobic residues.²⁸⁹ At high particle concentrations, ISVP* conversion is regulated by a positive feedback mechanism in which $\mu 1N$, which is released during ISVP* formation, promotes ISVP-to-ISVP* conversion of the remaining particles.³ Acceleration of ISVP* formation by $\mu 1N$ is dependent on temperature and target flexibility, suggesting that particle dynamics are required to expose a $\mu 1N$ interaction domain.³ Since such particle concentrations are unlikely to be achieved following a low-multiplicity viral infection, it remains unclear how these findings translate to ISVP* formation in cellular endosomes during viral entry.

Genetic studies using ethanol-resistant or thermostable mutants indicate that $\mu 1$ residues affecting the overall stability of the virus also regulate membrane-penetration efficiency.^{79,123,226,522} These and other stability-altering residues identified in thermostable reovirus mutants³²⁴ are located between residues 383 and 612 of $\mu 1$ and map to either domain IV that forms the jelly-roll β -barrel or the α -helical portions of domain III that lie just below the β -barrel structure. Since these $\mu 1$ domains participate in interactions between neighboring $\mu 1$ monomers, these residues are thought to modulate viral stability by preventing unwinding of the $\mu 1$ trimer.²⁸⁹ Consistent with an increase in $\mu 1$ protein rigidity in ethanol-resistant and thermostable mutants, viral cores recoated with mutant $\mu 1$ proteins, or recombinant reoviruses containing single amino acid substitutions in $\mu 1$ in an otherwise wild-type background, display diminished ISVP-to-ISVP* conversion and have defects in membrane penetration.^{79,121,123,226,324,430,522} These studies suggest that a central region of $\mu 1$ involved

in intermolecular interactions is an important regulator of the ISVP-to-ISVP* transition. In addition to these residues, changes in the C-terminal ϕ fragment also control viral stability³²⁴ and affect membrane penetration by reducing the efficiency of ISVP-to-ISVP* conversion.¹²¹ While it is not clear how ϕ residues modulate these properties, since both $\mu 1N$ and ϕ are released from the virus particle during ISVP* formation,²³⁸ it is likely that conformational rearrangements in $\mu 1$ during ISVP* formation are not restricted to the δ domain but also involve the $\mu 1N$ and ϕ domains. Therefore, amino acid substitutions within ϕ that negatively affect its conformational flexibility would likely prevent the $\mu 1$ reorganization required for ISVP* formation.

Pore Formation Mediated by $\mu 1N$ and ϕ

Reovirus forms small, size-selective pores in erythrocyte model membranes.² Both $\mu 1N$ and ISVP* associate with erythrocyte membranes,^{2,238} but $\mu 1N$ is capable of pore formation in the absence of other viral components.²³⁸ While ϕ also associates with membranes,²³⁸ its recruitment does not result in membrane penetration. These findings are consistent with the observation that viruses incapable of δ - ϕ cleavage can penetrate membranes and are fully infectious.^{80,83} Since pore formation by $\mu 1N$ is enhanced by the presence of ϕ , it is possible that ϕ functions as a $\mu 1N$ chaperone and facilitates membrane penetration by reovirus.²³⁸ Pores formed by released $\mu 1N$ fragments are considerably smaller than those required to allow the viral intermediate to traverse the membrane.² Therefore, it is not clear how pore formation in model membranes relates to membrane penetration during cell entry. Analogous to erythrocyte membrane rupture, pore formation may result in osmotic lysis of endosomes in which viral particles are present. Alternatively, the initial small pore formed by the virus might recruit cellular factors that produce larger pores or channels through which the viral intermediate can translocate.

Host Proteins Required for Membrane Penetration

Both the viral core and the δ fragment of $\mu 1$ are found in the cytoplasm following reovirus entry into host cells.⁸¹ While δ is found distributed diffusely throughout the cytosol, viral cores display a more punctuate cytoplasmic localization.⁸¹ These observations suggest that the δ fragment disassociates from the ISVP* during or immediately after membrane penetration. This idea is supported by evidence that reovirus cores are transcriptionally active in the cytoplasm and that activation of transcription requires removal of most of the $\mu 1$ fragments. Removal of δ from cores is thought to be accomplished by direct interaction of δ with the host chaperone Hsc70 via an ATP-dependent process.²³⁷ Based on evidence that chaperones can translocate proteins across membranes,⁵⁴² it is possible that concomitant with removal of particle-associated δ , Hsc70 also aids in transport of the viral core across membranes.²³⁷

Transcription

Reovirus core particles produced *in vitro* by proteolytic removal of outer-capsid proteins synthesize viral mRNAs representing each of the 10 gene segments when incubated with ribonucleotides and an ATP-regeneration system. During infection, transcriptionally active viral core particles produced following proteolytic disassembly and endosomal membrane penetration gain access to the cytosol and produce the initial wave of viral transcripts (primary transcripts) that encode new viral proteins. However,

in contrast to *in vitro*-generated transcripts, the primary viral transcriptome synthesized by entering viral particles during the first 4 to 5 hours of infection is biased towards transcripts from the L1, M3, S3, and S4 gene segments.⁵¹² One possible explanation for these observations is that transcriptionally active core particles in cells retain remnants of outer-capsid proteins or associate with cellular proteins that differentially repress transcription of some viral gene segments (presumably via allosteric effects). Alternatively, the stability of some viral transcripts in cells may depend on the presence of one or more of the $\lambda 3$, μ NS, σ NS, or $\sigma 3$ proteins encoded by the L1, M3, S3, and S4 gene segments, respectively. Notwithstanding this early difference in viral transcription, by 10 hours postinfection all of the viral transcripts are synthesized at frequencies proportional to their length.^{359,442,458} Primary transcription from particles entering cells peaks around 6 hours postinfection and is replaced by secondary transcription that results from newly assembled transcriptase particles. The large majority of viral mRNA is synthesized as a consequence of secondary transcription.

Cores as Molecular Machines

The viral core particle contains the genome and enzymes required to produce capped viral mRNAs. Each core contains 12 copies of the viral RdRp, $\lambda 3$, and ~ 24 copies of the polymerase co-factor, $\mu 2$. Electron micrographs of transcribing cores show viral mRNAs exiting at each of the fivefold symmetry axes.¹⁸⁷ Concordantly, all 10 gene segments can be transcribed simultaneously.⁴⁵⁸ Isolated $\lambda 3$ polymerase has limited enzymatic activity and likely must interact with its co-factor $\mu 2$ and the $\lambda 1$ shell protein to mediate native catalysis. RNA transcripts synthesized from the [–] strand template of the genomic dsRNA are extruded through a peripentonal channel in the $\lambda 1$ shell and enter a cavity formed by the pentameric $\lambda 2$ protein. As the nascent viral transcripts are extruded into and through the $\lambda 2$ turret, they are capped by guanylyltransferase and methyltransferase activities associated with $\lambda 2$ and then gain access to the cytosol.

Activation of Transcriptase Function

Transcription in intact, double-shelled virions is repressed. In the repressed state, the 3' end of each [–] strand template is probably unwound from the complementary [+] strand and held in a preinitiation complex with a polymerase molecule at the active site. In this conformation, the polymerase can only synthesize short abortive transcripts that represent the first 2 to 4 bases complementary to the 3' end of the [–] strand template. Indeed, $\sim 25\%$ of the total RNA found in reovirus virions represents short ssRNA oligonucleotides that are either abortive transcripts or nontemplated oligoadenylates that are likely synthesized during the last stages of virion morphogenesis as transcription is shut off by assembly of the outer capsid.^{39,41,248} The block appears to be at the stage of clearance of the promoter from the polymerase active site. Removal of outer-capsid proteins $\sigma 3$ and $\mu 1$ by proteolysis allows a conformational change in the core particle that permits opening of the C-terminal flaps of the $\lambda 2$ turret and release of $\sigma 1$.^{151,459} These changes are accompanied by activation of the transcriptase, which allows promoter escape and transcript elongation. However, 90% of cores generated *in vitro* synthesize only short abortive transcripts and are incapable of

transitioning from initiation to elongation.¹³⁴ The remaining 10% of cores (so-called C-fraction cores) synthesize full-length transcripts and, in these particles, elongation and not promoter clearance is the rate-limiting step in transcription. Mechanisms underlying these differences are not known, but the capacity of small molecules that modify the stability of RNA duplexes (e.g., DMSO and spermidine) to alter the percentage of cores capable of transcribing full-length transcripts suggests that global changes in the conformation of the RNA gene segments are required for activation of transcription.¹³⁴ This hypothesis is supported by the observation that the liquid crystalline RNA within transcriptionally active cores is less closely packed than genomic RNA within inactive cores, ISVPs, or virions.³¹⁹

The Transcriptional Cycle

Transcription of reovirus dsRNA gene segments is iterative and involves a well-orchestrated series of steps. The dsRNA gene segment first must be unwound to allow the 3' end of the [–] strand template to enter the catalytic site of the polymerase. The 3' end of the template strand is then specifically recognized and placed in register for priming and initiation of RNA synthesis. After RNA synthesis is initiated, the promoter region of the template must be cleared from the active site to allow the nascent RNA transcript to be elongated. As elongation proceeds, the transcript is separated from the template and extruded from the polymerase. The template exits the polymerase through a different polymerase channel and is likely rewound with its cognate [+] strand before having its 3' end guided back towards the template entry portal to allow efficient reinitiation of synthesis. Immediately after the nascent transcript exits the polymerase, the terminal γ phosphate at its 5' end is removed by an RNA triphosphate phosphohydrolase, and the transcript is passed into a cavity enclosed by the pentameric $\lambda 2$ turret where it is guanylated by a guanylyltransferase domain and 7'-N and 2'-O methylated by two independent methyltransferase domains. Finally, the capped RNA transcript exits the core particle into the cytosol.

Enzymatic Activities Associated with Transcription RNA-DEPENDENT RNA POLYMERASE ($\lambda 3$)

Twelve copies of the L1-encoded $\lambda 3$ RdRp (142 kDa, 1,267 aa) are encapsidated within each core particle.^{150,394,550} A 2.5 Å atomic resolution structure of $\lambda 3$ ⁴⁸³ reveals a central RdRp domain (aa 381–890) with canonical right-handed “thumb,” “palm,” and “fingers” subdomains (Fig. 44.10A). The catalytic cleft is enclosed (or “caged”) by an N-terminal domain (aa 1–380), which bridges the “fingers” and “thumb” subdomains, and by a C-terminal “bracelet” domain (aa 891–1267) (Fig. 44.10A). The $\lambda 3$ protein can be modeled as a rounded cube ~ 65 Å in diameter with channels on its front, bottom, rear, and left sides that allow access to the active site (Fig. 44.10B). These channels allow entry of the template and nucleoside triphosphates (NTPs) and exit of the minus-strand template or dsRNA product and the plus-strand transcript (Figs. 44.10C and D).

Crystal-soaking experiments with a cap analog identified a putative cap-binding site on the outside of the polymerase⁴⁸³ (Fig. 44.10B). The 5' cap of the [+] strand RNA likely remains anchored in this position close to the template entry channel (Fig. 44.10C). This placement would retain the 3' end of the [–] strand template RNA in a position where it could easily

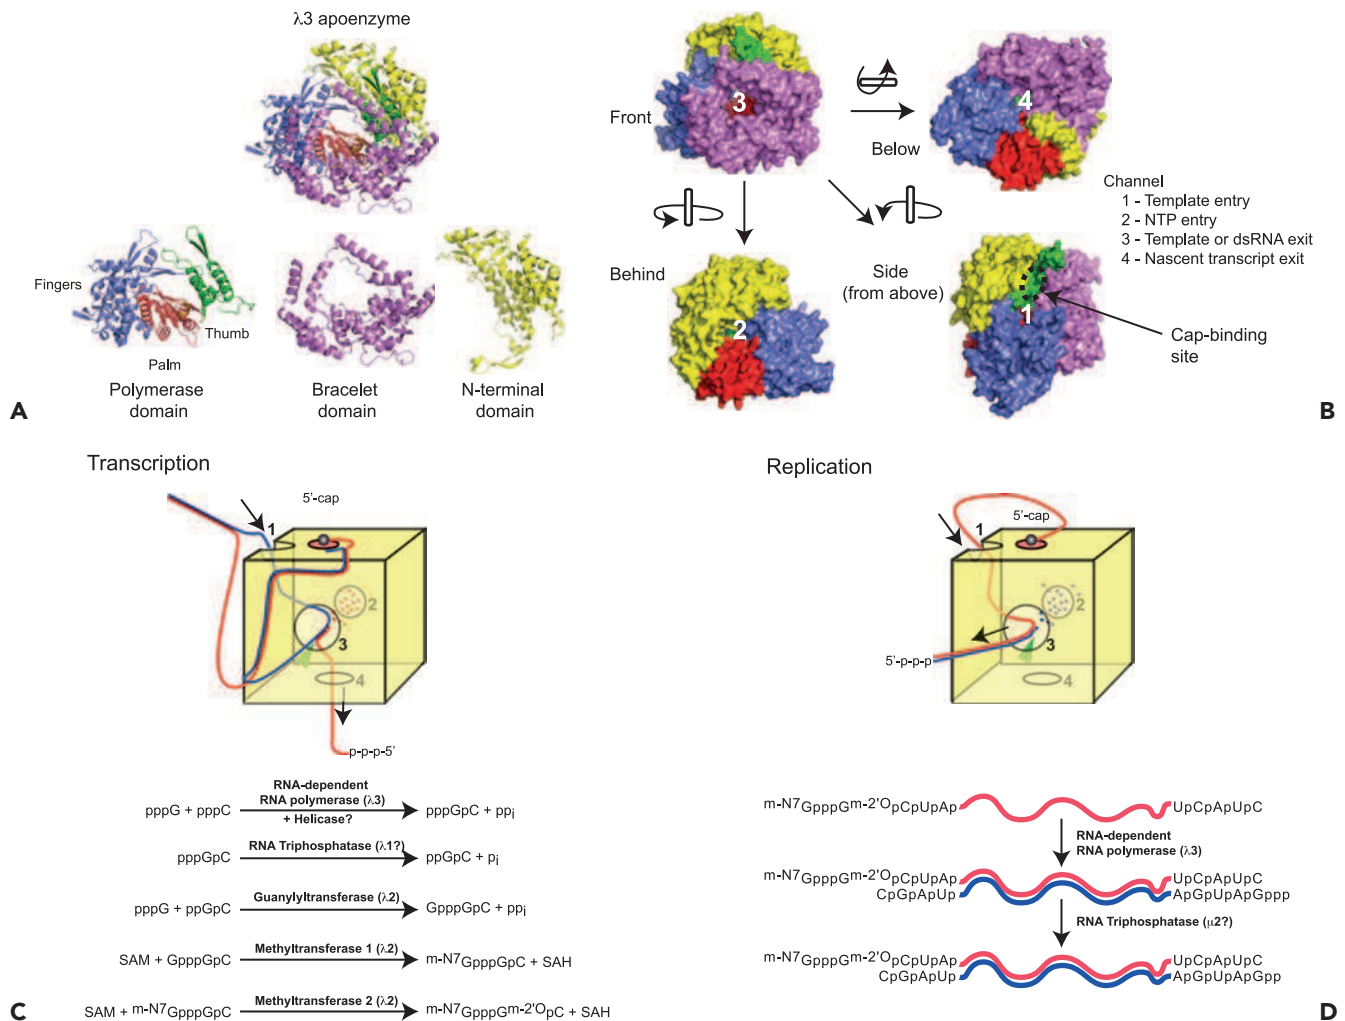

FIGURE 44.10. The reovirus $\lambda 3$ RNA-dependent RNA polymerase and its enzymatic actions. **A:** Ribbon diagram of the crystal structure of the $\lambda 3$ apoenzyme.⁴⁸³ Access to the central conserved polymerase domain is limited by the N-terminal domain (yellow) and C-terminal bracelet domain (purple), which form channels. **B:** Space-filling model of the polymerase with the channels that allow (1) template entry, (2) NTP entry, (3) template or dsRNA exit, and (4) nascent transcript exit indicated. The 5' cap of the template mRNA binds to the polymerase close to the template entry site. The enzymatic activities of $\lambda 3$, transcription (**C**) and replication (**D**), and the movement of the template minus-strand RNA (blue) during transcription or template positive-strand mRNA (red) during replication are shown in the schematic. Other enzymatic activities associated with transcription and replication are indicated below each schematic.

access the polymerase active site. An unusual feature of $\lambda 3$ that is also shared by the rotavirus VP1 polymerase is the presence of a priming loop that engages the incoming priming NTP during initiation. This loop is displaced toward the “palm” sub-domain during elongation. Failure of the loop to move would prevent elongation and might explain the large number of abortive transcripts within viral cores. Thus, the priming loop may be a kinetic barrier to the transition from initiation to elongation during transcription.^{93,134,318}

Comparison of the rotavirus VP1 and reovirus $\lambda 3$ polymerase structures reveals a difference in the location of the priming loop of VP1, which is bent away from the active site, and in this conformation would not be capable of stabilizing an incoming NTP and initiating RNA synthesis. The VP1 polymerase also differs from $\lambda 3$ in that it specifically recognizes and binds the 3'

end of the [+] strand RNA but not the 3' end of the [-] strand RNA. The $\lambda 3$ protein displays limited specificity for binding the 3' end of the RNA. However, the RNA template is held in precise register for the initiation of synthesis from the end of the template.³¹⁸ This arrangement contrasts with the specific recognition of the 3' end of the [+] strand RNA by VP1 that paradoxically places the template out of register.²⁹³ One attractive hypothesis is that the two structures represent different conformers, with VP1 being in the inactive state found prior to packaging of viral mRNA into cores. In this case, specific recognition of the 3' end together with cap binding would create mRNA–polymerase complexes, but initiation of synthesis of the partner dsRNA presumably would be prevented until a conformational change in the polymerase occurs concurrent with assortment and packaging of a complete set of viral

mRNAs.³¹⁷ The $\lambda 3$ structure would represent the active form of the polymerase found within transcriptionally competent cores, where specific recognition is not absolutely required, but it is imperative that initiation begins at the first residue of the template. RNA synthesis is fully conservative²¹³ and initiates with entry and correct registration of the 3' end of a template RNA at the active site.⁴⁸³

HELICASE ACTIVITY

An unwinding, or helicase, activity is required to separate the genomic dsRNA [+] and [-] strands prior to transcription and to facilitate rewinding of the template [-] strand with the [+] strand after it exits the polymerase. Although semipurified $\lambda 1$ protein has helicase activity *in vitro*,⁵² the viral protein responsible for helicase activity during infection is thought to be $\lambda 3$.⁴⁸³ The presence of a cap-binding site on $\lambda 3$ would allow strand separation to occur. In addition, a loop present in the bracelet subdomain of the $\lambda 3$ polymerase may aid in separation of the template and transcript during transcription.⁴⁸³

RNA TRIPHOSPHATE PHOSPHOHYDROLASE ACTIVITY

Following transcription, the terminal γ phosphate at the 5' end of the transcript is removed, yielding a diphosphate to initiate capping. The $\lambda 1$ -encoded $\lambda 1$ protein (142 kDa, 1275 aa) has phosphohydrolase activity,⁵¹ and removal of the γ phosphate likely occurs as the transcript is directed out of the core particle through pores in the $\lambda 1$ shell.⁵⁵⁰ The passage of the transcript through $\lambda 1$ may be facilitated by the RNA-binding activity associated with a $\lambda 1$ N-terminal domain.⁵² Alternatively, or in addition, the capacity of $\lambda 1$ to bind RNA may be important during assortment of viral mRNAs for packaging.

GUANYLYLTRANSFERASE AND METHYLTRANSFERASE ACTIVITY

Following removal of the 5' γ -phosphate from the transcript, a guanylyltransferase associated with the N-terminal domain of the $\lambda 2$ -encoded $\lambda 2$ protein (144 kDa, 1288–1289 aa) adds a guanylate cap to the 5' diphosphate of the transcript using GTP as a substrate.^{106,296} The transcript is then further modified by the addition of 7-*N* and 2'-*O* methyl groups by the two methyltransferase subdomains of $\lambda 2$.⁴⁸³ The methyl donor comes from S-adenosyl methionine (SAM), which is converted to S-adenosyl-L-homocysteine after the methyl group is transferred to the cap.²⁹⁵ Five $\lambda 2$ monomers form a turret-like structure that projects distally from the $\lambda 1$ shell. The long axis of each $\lambda 2$ monomer lies at an angle of approximately 45° to the fivefold axis of symmetry. The $\lambda 2$ monomers wrap around each other to form a hollow cylinder, approximately 70 Å in diameter at its base, with C-terminal flaps at the top that narrow to approximately 15 Å.³⁹⁴ The N-terminal guanylyltransferase domains (residues 1–385) of the five $\lambda 2$ monomers are located at the base of the turret. Lysine residues at positions 171 and 190 in the $\lambda 2$ sequence are required for enzymatic function and project into the active site.²⁹⁶ The guanylyltransferase domain is linked by a small domain (residues 386–433 and 690–802) to two methyltransferase domains (methylase 1, residues 434–691, and methylase 2, residues 804–1022), each possessing a SAM-binding site.³⁹⁴ Based on their location, it is hypothesized that methylase 1 catalyzes guanosine-7-*N*-methylation and methylase 2 catalyzes guanosine-2'-*O*-methylation. The flap of the $\lambda 2$ turret is formed by the C-terminal 250 residues that form three immunoglobulin-like folds.³⁹⁴

Location of $\lambda 3$ Within Core Particles

A 7.6 Å cryo-EM image reconstruction of viral core particles shows that each $\lambda 3$ polymerase lies close to but slightly adjacent from the fivefold symmetry axes.⁵⁵⁰ The transcript-exit channel (Fig. 44.10B) faces towards a peripentonal channel in $\lambda 1$, suggesting that the phosphohydrolase activity of $\lambda 1$ is responsible for removal of the γ phosphate from nascent transcripts. The location of $\mu 2$ has not been resolved, but two copies of $\mu 2$ are thought to associate with each $\lambda 3$ polymerase.⁵⁵⁰

Role of $\mu 2$ in Transcription

The M1-encoded $\mu 2$ protein (83 kDa, 736 aa) is found in approximately 24 copies within each core particle. It interacts with the $\lambda 3$ polymerase and may also interact with $\lambda 1$. Like many reovirus core proteins, $\mu 2$ binds ssRNA and dsRNA.⁶³ It has NTPase and RNA 5' triphosphatase activity and contains an A-box NTP-binding motif. The $\mu 2$ protein is thought to be a co-factor for the $\lambda 3$ polymerase. The $\mu 2$ RNA 5' triphosphatase activity may be required for removal of the 5' γ phosphate from newly synthesized [-] strand RNA during dsRNA synthesis. A role for $\mu 2$ in transcription is inferred from genetic studies indicating that the $\mu 2$ -encoding M1 gene segment segregates with strain-specific differences in the optimum temperature of transcription.⁵⁴⁰ The $\mu 2$ NTPase and RTPase activities are required for viral replication, as ectopic expression of mutant $\mu 2$ proteins lacking NTPase or RTPase activity (K415A or K419A) fails to complement siRNA-mediated knockdown of wild-type $\mu 2$.²⁶³

Translation and Viral Factory Formation

Translation of Reovirus mRNAs and Viral Protein Synthesis

Early studies of eukaryotic translation initiation used reovirus mRNAs synthesized by viral core particles *in vitro* to show an association of mRNA with ribosomes.^{268,270,271} From these studies, reovirus mRNAs were found to have 5' terminal sequences blocked or capped by a 7-*N*-methylguanosine linked 5' to 5' with a conserved GpCpUpA sequence.^{268,271} The 7-*N*-methylguanosine cap is required for efficient recognition of reovirus mRNAs by 40S ribosomal subunits.²⁷¹ However, nucleotide sequences that vary between gene segments also contain structural information required for efficient association of reovirus mRNAs with ribosomes.⁴⁰⁶ The structural information contained in the 5' sequences of reovirus mRNAs also may be important determinants of viral host range, as avian reovirus transcripts do not initiate protein synthesis in mammalian cells.^{43,304}

Unlike host mRNAs, reovirus mRNAs lack poly(A) tails and have relatively short 3' NTRs (35–83 nt) that terminate with UpCpApUpC-3'. A poly(A) tail is thought to promote translation by stabilizing mRNA and facilitating translational reinitiation by ribosomes as a consequence of mRNA circularization via interactions of the poly(A)-binding protein with the 3' poly(A) sequence and eIF-4G, which binds the cap-binding protein, eIF-4E.⁵²⁰ A similar mechanism for reovirus translation has not been found but is postulated.³⁴⁸ Translation enhancing and repressing elements are present in the 3' NTR of the *s4* mRNA,³³⁶ which is the most efficiently translated viral transcript.¹⁹ It is likely that such elements also are present in the 3' NTRs of other segments. The 3' NTR of *s4* mRNA is bound by cellular proteins that may be involved in translational control.³³⁶

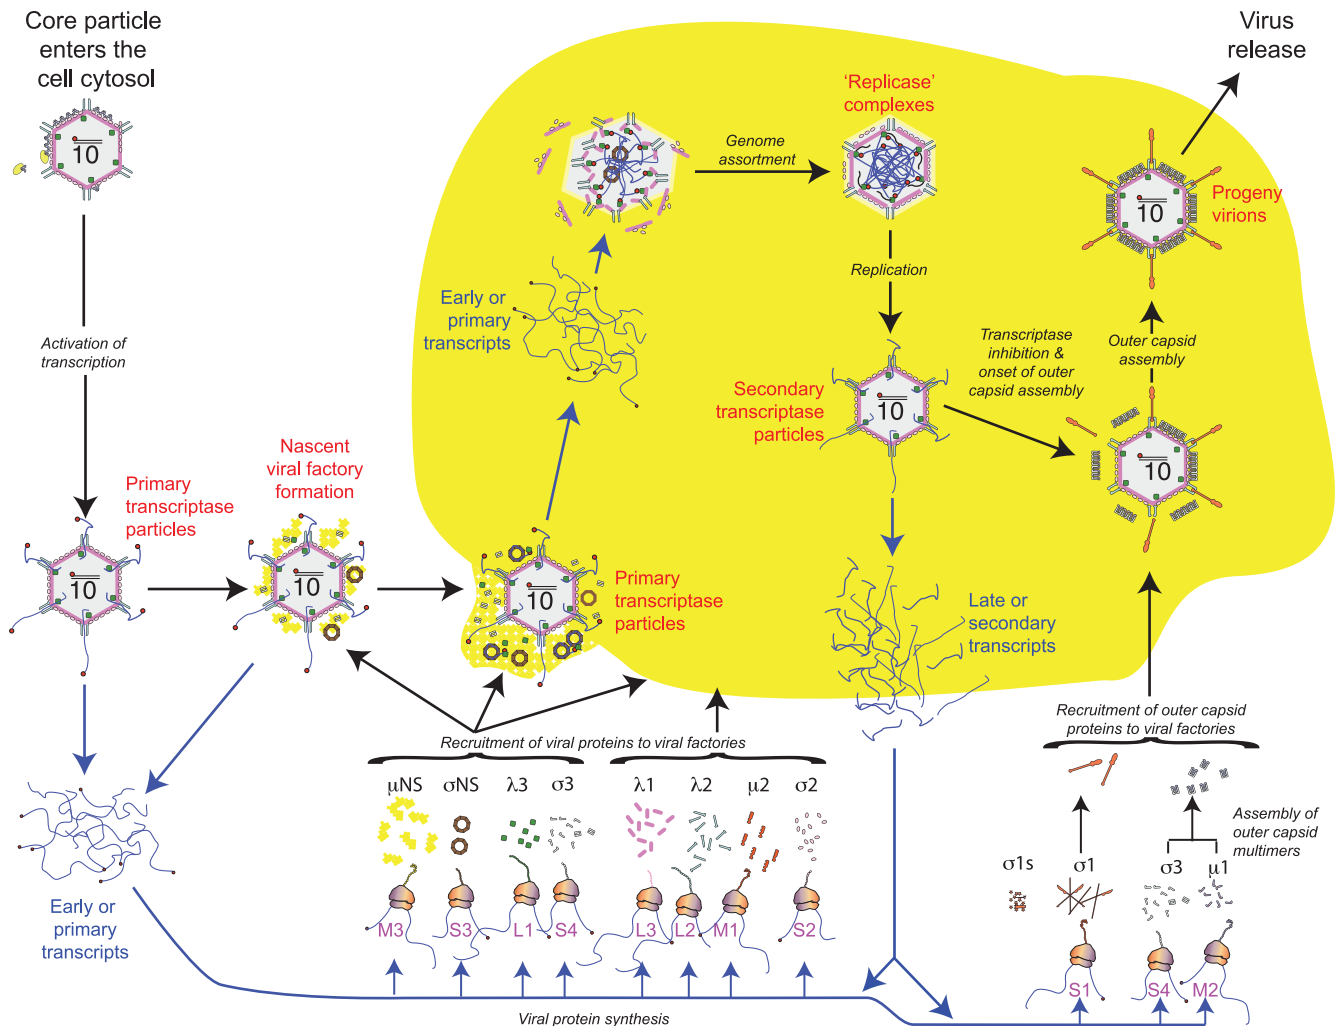

FIGURE 44.11. Schematic of reovirus genome replication and assembly. Following virus entry, a transcriptionally active sub-viral particle (primary transcriptase particle) is deposited in the cytoplasm and begins synthesis of capped viral transcripts (early or primary transcripts). The viral transcripts encode viral proteins, including the nonstructural protein μ NS, which surround and enclose the primary transcriptase complex to form a nascent viral factory (VF) also called a viral inclusion body (indicated in yellow). A subset of viral proteins (μ NS, σ NS, λ 3, and σ 3) may be synthesized early and are recruited to VFs. Assembly of new virions begins with the assortment of each of the 10 primary transcripts together with the viral structural proteins that form core particles (λ 1, λ 2, λ 3, μ 2, and σ 2). The details of this process are unknown but may involve binding of the 5' cap of the viral mRNA and its 3' end to a viral replicase complex, which may be formed by λ 1, λ 2, λ 3, and μ 2. Stoichiometric assortment of each of the 10 viral mRNAs into a complex is thought to require specific RNA–RNA interactions. Only single molecules of each of the 10 mRNA species are packaged. Following assortment, a putative “replicase” complex forms that rapidly replicates each of the viral mRNAs to form the 10 dsRNA genome segments. This process is accompanied by condensation of the viral core proteins to form a nuclease-resistant secondary transcriptase particle. During infection, the majority of viral transcripts are produced by secondary transcriptase particles. These transcripts are not incorporated into new virus particles, perhaps because they lack a cap. In a poorly understood process, the transcriptase activity of the secondary transcriptase particles is inhibited, and the viral outer-capsid proteins μ 1, σ 3, and σ 1 are added to the core particles to form progeny virions. Progeny virions are then released from the infected cells using a poorly understood process that may involve lysis of some cell types. Blue lines and arrows indicate movement of viral RNA. Black arrows indicate sequential steps.

Reovirus core particles synthesize m^7G -capped viral mRNAs both *in vitro* and in infected cells. Capped viral mRNAs are synthesized early after infection by core particles introduced into the cytosol following disassembly (Fig. 44.11). However, as infection progresses in at least some types of cells, such as mouse L929 cells, there is a transition from capped to uncapped viral mRNAs that have the structure [5'-pGpC...]

with uncapped viral mRNAs being first detected approximately 4 to 6 hours postinfection and peaking approximately 12 hours postinfection.⁴⁶⁰ The uncapped viral mRNAs are translated much more efficiently than capped viral or host mRNAs in extracts from infected L929 cells collected 10 hours postinfection.⁴⁶⁰ Addition of the σ 3 protein to lysates prepared from uninfected L929 cells substantially increases the efficiency

of uncapped viral mRNA translation.²⁸¹ The mechanism by which $\sigma 3$ enhances the preferential translation of uncapped viral mRNAs is not known, but $\sigma 3$ may function to modify the activity of a translational initiation factor such that it recognizes uncapped viral mRNAs. Core particles also transcribe uncapped viral mRNAs *in vitro* to varying extents depending on the reaction conditions.¹⁸⁰ It is possible that uncapped mRNAs are synthesized in cells by progeny viral core particles.⁵⁴⁵ Unlike the core particles that initiate infection, progeny core particles have repressed guanylyltransferase and methyltransferase activities. Interestingly, the guanylyltransferase and methyltransferase activities of progeny core particles can be stimulated by chymotrypsin,⁴⁵⁹ suggesting that these activities are triggered by viral disassembly. Although the evidence for uncapped viral mRNAs in L929 cells is compelling, uncapped viral mRNAs are not found in SC-1 cells.¹⁴¹ These differences may be attributable to differences in methodology or to cell type-specific effects on viral transcription.

The 10 reovirus gene segments encode mRNAs for synthesis of 12 viral proteins (Table 44.4 and Fig. 44.11). Viral protein synthesis gradually increases during infection with a concomitant decrease in cellular protein synthesis⁴⁴⁰ (see Responses of the Host Cell to Infection—Inhibition of Cellular RNA and Protein Synthesis and Induction of Cellular Stress Responses). Synthesis of viral proteins can be detected as early as 2 to 3 hours after infection. However, because the L1, M3, S3, and S4 gene segments are transcribed before the other gene segments, the $\lambda 3$, μ NS, σ NS, and $\sigma 3$ proteins encoded by these gene segments will be synthesized early.²⁷⁶ By approximately 10 hours postinfection, most of the proteins synthesized within infected cells are viral in origin. The rates of synthesis of the individual proteins vary, but their relative levels remain constant throughout infection.

For example, the $\mu 1$ protein, the major outer-capsid protein, is synthesized at 20-fold greater levels than the $\sigma 1$ protein despite only a twofold difference in mRNA levels.

Translation of reovirus transcripts is tightly regulated.²⁴⁸ Some of the factors that influence the differential rates and frequencies of translation of reovirus mRNAs include: (1) nucleotide sequences at the -3 and $+4$ positions flanking the AUG start codon; (2) length of the 5' NTRs, which may affect translation rate (those with the longest 5' NTRs are translated most efficiently); (3) conserved sequence motifs that extend beyond the 5' and 3' NTRs within the mRNA, which may recruit specific translation initiation factors; (4) transcript length, which influences translational frequency (shorter transcripts are translated at higher levels); and (5) cellular and viral RNA-binding proteins. The viral σ NS,¹⁸⁶ μ NS,¹⁵ and $\sigma 3$ ²³¹ proteins bind ssRNA, and within viral assembly sites, all or a subset of these proteins may preferentially retain viral transcripts. In addition, stress granules are induced early after reovirus infection³⁸⁴ (see Responses of the Host Cell to Infection—Inhibition of Cellular RNA and Protein Synthesis and Induction of Cellular Stress Responses). The induction of stress granules requires disassembly of virions but does not require *de novo* synthesis of viral RNA or protein. However, the recruitment of entering core particles to stress granules requires viral transcription.³⁸⁴ It is not clear whether transcripts synthesized within stress granules are eventually translated.

Viral Factories

Reovirus replication and assembly occur within cytoplasmic structures called viral factories (VFs) or viral inclusion bodies (VIBs) (Figs. 44.11 and 44.12). VFs are first observed as round punctate structures 2 to 4 hours postinfection, then increase in

FIGURE 44.12. Reovirus forms inclusion complexes in infected cells. Most reovirus strains (e.g., type 1 Lang [T1L], *top*) form filamentous inclusions (also called viral factories or viral inclusion bodies) within infected cells that are associated with the microtubular cytoskeleton. However, a few strains (e.g., type 3 Dearing [T3D], *bottom*) form globular inclusions due to a temperature-sensitive mutation in the $\mu 2$ protein (P208S). To obtain these images, LLPCk cells expressing GFP-tubulin were stained with an antiserum specific for viral nonstructural protein μ NS, which localizes to inclusions, at 24 hours postinfection. The μ NS protein is shown in *red*, and GFP-tubulin, which marks microtubules, is shown in *green*.

size over time.^{33,68,373} In some infected cells, VFs occupy greater than 50% of the cytosol by 24 to 48 hours postinfection and completely surround the nucleus. Reovirus VFs initially appear as globular structures (Parker and Nibert, unpublished). However, VFs of most strains appear filamentous in morphology by ~12 hours postinfection as a consequence of their association with stabilized microtubules (373; Parker and Nibert, unpublished). In thin-section electron micrographs, VFs contain both assembling and complete viral particles embedded within a matrix composed of thin, kinked fibrils.¹¹⁹ VFs exclude ribosomes and most cellular organelles and are not surrounded by membranes. Microtubules are incorporated into VFs and responsible for the filamentous appearance of VFs formed by most reovirus strains.³⁷³

The VF matrix is formed by the M3-encoded nonstructural protein, μ NS (80 kDa, 721 aa) (Fig. 44.12). Ectopic expression of μ NS leads to formation of globular structures in the cytoplasm that are similar to the VFs formed by reovirus strain T3D.⁶⁸ The C-terminal 250 amino acids (aa 471–721) of μ NS is the minimal region required for formation of these structures.⁶⁵ This region of μ NS contains two predicted coiled-coil regions flanked by a linker that contains a predicted CCHC Zn-binding motif. This motif is required for formation of structures with the morphology of VFs. The μ NS protein specifically interacts with and recruits the viral structural proteins found in core particles (λ 1, λ 2, λ 3, μ 2, and σ 2) and the RNA-binding nonstructural protein σ NS^{66,68,325,326} (Fig. 44.11). These activities may promote efficient assembly of nascent viral transcriptase particles. The capacity of σ NS to be recruited to VFs is partially dependent on its capacity to bind RNA.³²⁶ Newly synthesized viral RNAs are localized to VFs.³²⁵ The regions of μ NS responsible for interacting with viral core proteins have been mapped to specific nonoverlapping regions of the protein.³²⁵

VFs are thought to promote virus replication and assembly by sequestering and concentrating viral RNA and structural proteins (Fig. 44.11). In addition, VFs may protect viral RNA from recognition by the intracellular pattern-recognition receptors, RIG-I and Mda-5. The N-terminal region of μ NS (aa 1–41), which interacts with viral structural protein μ 2^{68,325} and nonstructural protein σ NS,³²⁶ is required for viral replication, as a truncated version of μ NS lacking these residues does not complement siRNA-mediated knockdown of wild-type μ NS.²⁶³ An N-terminally shortened version of μ NS called μ NSC that lacks the first 40 amino acids of μ NS is synthesized in infected cells.²⁷⁸ It is proposed that μ NSC is synthesized as a consequence of translation initiation from an alternative, in-frame start codon in the *m3* mRNA.⁵²⁵ The function of μ NSC in infected cells is not known, but it is not required for viral replication.²⁶³ It also is not known how outer-capsid proteins μ 1, σ 3, and σ 1 are recruited to VFs. However, it is apparent from immunofluorescence images that these proteins are present in these structures (33,34; Coffey and Parker, unpublished).

The vast majority of viral transcripts are likely synthesized and extruded from transcriptionally active viral particles buried within the μ NS matrix of VFs (Fig. 44.11). When purified viral core particles and μ NS are mixed *in vitro*, the μ NS protein polymerizes around the core particles and prevents them from being coated with outer-capsid proteins.⁶⁷ Recoating of cores with outer-capsid proteins inhibits transcription.¹⁶⁷ However, cores buried within the μ NS matrix are capable of transcription when provided with suitable substrates and an energy regeneration

system.⁶⁷ It is likely that incoming transcriptionally active core particles become embedded within nascent VFs following synthesis of μ NS, as genome-lacking cores rapidly become embedded within μ NS VF-like structures when they enter the cytosol of cells ectopically expressing μ NS.⁶⁶ Thus, μ NS appears to protect the incoming viral cores that catalyze primary transcription from being prematurely inactivated by the addition of *de novo* synthesized outer-capsid proteins.

The VF matrix protein μ NS contains a conserved C-terminal clathrin-box motif (711-LIDFS-715) that recruits clathrin heavy and light chains to VFs. Cellular functions dependent on clathrin, including endocytosis and secretion, are inhibited in cells infected with wild-type reovirus but not a recombinant reovirus mutant with a leucine-to-alanine substitution at position 711 of μ NS (μ NS-L711A).²³⁹ The μ NS-L711A mutant displays only mildly impaired replication efficiency and normal VF formation. Reovirus-induced inhibition of viral endocytosis and secretion is modest and correlates with VF size in infected cells, and thus occurs late in infection. It is possible that sequestration of clathrin in VFs and concomitant inhibition of endocytosis prevents superinfection of cells.²³⁹

The viral μ 2 protein binds to and stabilizes microtubules.^{256,373} In addition, μ 2 binds to μ NS, which links the VF matrix to the microtubule cytoskeleton.^{68,373} One isolate of T3D used in many laboratories does not form filamentous VFs but instead forms globular VFs⁶⁸ (Fig. 44.12). This change in VF morphology is a consequence of a temperature-sensitive mutation in μ 2 (P208S). In cells grown at 31°C, T3D forms filamentous VFs. However, at 37°C, T3D VFs are globular, and the μ 2 protein is ubiquitinated and targeted for proteasomal degradation.³²⁷ Despite this defect, the T3D μ 2 allele appears to function adequately as a co-factor for the λ 3 polymerase within core particles, as there is no significant impairment in the capacity of this strain to infect cultured cells or cause disease in mice. The association of μ 2 with microtubules is not required for VF formation, as dissolution of microtubules by treatment with nocodazole does not reduce viral titer in tissue culture.³⁷³

Genome Assortment and Replication

The process by which the reovirus gene segments are assorted and packaged into nascent viral cores is a major mystery. The fidelity of packaging and the lack of evidence of mispackaging suggest a specific mechanism. It is thought that equimolar amounts of each of the viral mRNAs associate with nonstructural proteins and structural proteins of the core, then condense to form a replicase particle that copies the [+] strand mRNA yielding a [–] strand partner for each of the 10 RNA gene segments.¹⁵ Soon after synthesis, viral [+] strands associate with μ NS, σ NS, and σ 3. The association of core protein λ 2 with these RNA-protein complexes occurs concurrently with the onset of [–] strand synthesis.¹⁵ It is possible that mRNAs representing each gene segment are complexed with the λ 3 polymerase to form circular RNAs via interactions of the 5′ cap with the polymerase cap-binding site and the 3′ terminus with the polymerase template-binding site. Specific assortment and condensation of the RNAs would then presumably be driven by RNA–RNA interactions, perhaps aided by viral core proteins λ 1, λ 2, and μ 2.

Assembly and Release

Little is known about how reovirus particles are assembled in infected cells. Complete and incomplete viral particles are

observed in VFs by electron microscopy. Synthesis of dsRNA likely occurs in parallel with core assembly, as conditions that inhibit polymerase activity in cells yield core-like particles that contain less than complete dsRNA genome complements.^{1,425} Assembly of the outer capsid likely occurs following assembly of the core (Fig. 44.11). However, outer-capsid shells can assemble in the absence of fully formed cores, as such shells are observed by electron microscopy following replication of some temperature-sensitive reovirus mutants at restrictive temperatures.¹⁷⁰ It is not understood how the outer-capsid proteins condense onto cores in cells. Recoating of core particles with outer-capsid proteins *in vitro* inhibits transcription at the level of elongation.¹⁶⁷ Assembly of the outer capsid onto cores may be regulated in cells to prevent premature termination of transcription. Cellular chaperones distributed to VFs may act to promote specific viral assembly steps.

Empty core-like particles form in cells that express the $\lambda 1$, $\lambda 2$, and $\sigma 2$ proteins or the $\lambda 1$, $\lambda 2$, $\lambda 3$, and $\sigma 2$ proteins. Minimally, a shell will form if $\lambda 1$ and $\sigma 2$ are co-expressed; $\lambda 3$ can be incorporated if it is co-expressed with $\lambda 1$ and $\sigma 2$.⁵³⁵ The pentameric $\lambda 2$ turret cannot assemble when $\lambda 2$ is expressed alone,³⁰⁵ suggesting that formation of a shell or partial shell by the $\lambda 1$ and $\sigma 2$ proteins is required to precipitate oligomerization of $\lambda 2$. “Spikeless” shells that lack the $\lambda 2$ protein assemble in cells infected with temperature-sensitive mutant tsA279, which carries a mutation in the $\lambda 2$ -encoding L2 gene segment, at the restrictive temperature.²¹⁵ Since the $\lambda 2$ protein also can interact with $\lambda 3$,⁴⁷⁰ it is possible that assembly of the core involves a complex of $\lambda 3$ (associated with viral [+] strand RNA) with a pentamer of $\lambda 2$ interacting with a partial shell of $\lambda 1$ and $\sigma 2$.⁵³⁵

The reovirus outer capsid consists of 200 heterohexameric assemblies of the $\mu 1$ and $\sigma 3$ proteins arranged in a T = 13 *laevo* lattice.²⁸⁹ Co-expression of $\mu 1$ and $\sigma 3$ in insect cells leads to formation of $\mu 1:\sigma 3$ heterohexamers that can assemble onto cores *in vitro*.⁸³ Isolated $\sigma 3$ crystallizes as a dimer and may bind to dsRNA in that conformation.³⁶⁸ The $\mu 1:\sigma 3$ heterohexamer structure (Fig. 44.9) suggests that $\mu 1$ monomers must form trimers before addition of $\sigma 3$ monomers to each of the $\mu 1:\mu 1$ interfaces.²⁸⁹ This structural evidence suggests that $\sigma 3$ can exist in two conformations, dimers and monomers. Of note, $\sigma 3$ becomes sensitive to proteolysis when complexed with $\mu 1$ to form $\mu 1:\sigma 3$ heterohexamers,⁴⁴⁶ suggesting that such conformers exist.

The trimeric $\sigma 1$ attachment protein requires cellular chaperones Hsc70 and Hsp90 for assembly.^{188,282} Assembly of the trimeric $\sigma 1$ protein as part of the outer capsid requires that the $\lambda 2$ turret initially be open and then close to lock the $\sigma 1$ tail into place. This assembly reaction also may require cellular chaperones. The encapsidation of $\sigma 1$ onto virions presumably occurs within VFs, but this is not known. Interestingly, the cellular chaperone Hsc70 also specifically associates with the μ NS viral matrix protein in a manner that does not require its chaperone activity.²⁵¹

Mechanisms governing reovirus egress from infected cells are not understood. It is possible that virus is released from some types of cells following lysis, but how this occurs is not known. A large quantity of infectious virus remains associated with cellular debris following cell death,⁴⁶⁶ perhaps in association with VF matrices. Reovirus-induced apoptosis also

may promote virus release from infected cells,³⁰⁷ although the mechanism of such an egress pathway is unclear.

RESPONSES OF THE HOST CELL TO INFECTION

Interferon Induction and Effects on Viral Replication

Activation of cellular sensors during infection by many types of viruses leads to recruitment of adaptor proteins and consequent stimulation of transcription factors ATF-2/c-Jun, interferon regulatory factor-3 (IRF3), and NF- κ B that induce transcription and secretion of type I IFNs (IFN- α 4 and IFN- β) (Fig. 44.13). Secreted IFN binds to IFN- α/β receptors on the surface of infected and surrounding cells and, by so doing, activates Jak1 and Tyk2 kinases that phosphorylate and activate the transcription factors STAT1 and STAT2. Activated STAT1 and STAT2 associate with IRF9 to form the heterotrimeric ISGF3 transcription factor complex, which translocates to the nucleus to induce transcription of hundreds of interferon-stimulated genes (ISGs), some of which are antiviral, and one of which, IRF7, is a latent transcription factor (Fig. 44.13). When IRF7 is activated by virus-induced phosphorylation, it can form homodimers or heterodimers with IRF3 to induce multiple IFN- α subtypes and further induce IFN- α 4 and IFN- β in a positive amplification loop.

Reovirus induction of IFN requires virion RNA, as fully assembled double-layered viral particles lacking the dsRNA genome (empty particles) fail to activate IRF3/7 or induce IFN.^{225,274} However, viral replication is dispensable for activation of IRF3/7.²²⁵ IRF3 is required for reovirus induction of IFN- β in at least some cell types,^{224,357} while IRF1, a related IRF, is not.²⁰ While one study demonstrated that reovirus activation of IRF3/7 requires the sensor RIG-I and its adaptor IPS-1,²²⁵ other studies demonstrated that reovirus-induced expression of ISGs can be mediated by either RIG-I or the related sensor MDA-5.^{250,291} This discrepancy may reflect cell type-specific differences or the assessment of different indicators (IRF3/7 vs. ISGs). Indeed, in myeloid dendritic cells, IFN induction by reovirus requires the helicases DHX9⁵⁵² and a complex of the helicases DDX1, DDX21, and DHX36, and the adaptor molecule TRIF.⁵⁵¹ Activation of NF- κ B requires IKK α and IKK γ /Nemo²⁰⁹ and is not dependent on RIG-I or IPS-1,²²⁵ suggesting a different trigger for stimulation of this innate immune response transcription factor. RIG-I and MDA-5 can be activated by reovirus dsRNA gene segments of different lengths.²⁵⁰ However, it is not clear how the viral gene segments might be exposed during reovirus replication. It is possible that RIG-I is activated by release into the cytosol of the short oligonucleotides present in reovirus particles. At least a portion of these oligonucleotides contain an unmodified 5' triphosphate group,³⁸ which might stimulate RIG-I.³⁷⁷

Reovirus induces secretion of IFN- β in immortalized cells^{274,461} and primary cell cultures.^{199,452} However, the degree to which reovirus induces IFN is in part dependent on cell type. For example, reovirus induces significantly more IFN- β in cardiac myocytes than in cardiac fibroblasts *in vitro*⁴⁷⁴ and *in vivo*,²⁸⁸ likely as a consequence of differences in the basal expression of components of the IFN response in these cells.⁵⁵⁵

FIGURE 44.13. Reovirus induces interferon expression and represses interferon signaling. Reovirus activation of IRF3 and NF-κB for induction of interferon (IFN) is cell type–specific and utilizes several pathways. Reovirus activates RIG-I or Mda-5, which then stimulate IPS-1 to induce phosphorylation and activation of transcription factor IRF3. Reovirus activation of NF-κB does not require RIG-I or IPS-1. Reovirus also activates DDX1/DDX21/DHX36 and TRIF to induce IFN. Reovirus strain-specific differences in the induction of IFN are associated with the *M1*, *L2*, and *S2* gene segments, which encode μ2, λ2, and σ2, respectively. Reovirus strain-specific differences in sensitivity to IFN are associated with these same gene segments. A single amino acid polymorphism in μ2 determines the capacity of this protein to repress IFN signaling, which affects induction of antiviral genes and further induction of IFN through a positive amplification loop. The σ3 protein is an RNA-binding protein that influences viral induction of IFN. Dotted arrows indicate indirect pathways (TRIF, kinases) or pathways that occur later in infection for induction of additional IFN (amplification loop). Question marks indicate unknown proteins or unknown functions.

Reovirus induces detectable levels of only a subset of IFN-α subtypes in cardiac cells.²⁸⁸

Differences in the induction of IFN by reovirus are also strain dependent. Reovirus T3D induces significantly more IFN than does T1L in cardiac myocytes; this difference segregates with the *M1*, *S2*, and *L2* gene segments.⁴⁵² The *M1*-encoded μ2 protein from T1L but not from T3D represses IFN signaling.⁵⁵⁶ Repression is associated with alterations in the transcription factor IRF9,⁵⁵⁶ but the mechanism underlying the repression is not known. A single amino acid polymorphism at μ2 residue 208 (proline in T1L, serine in T3D) determines the capacity of these viruses to repress IFN signaling.²³⁵ Interestingly, this polymorphism in μ2 also is responsible for strain-dependent differences in the morphology of VFs and levels of ubiquitylation of μ2³²⁷ (See Replication—Viral Factories). The μ2 protein may modulate IFN levels by repressing IFN-induced IRF7, thus

preventing further induction of IFN. Indeed, mutation of this repressor function alters reovirus induction of IFN-β.²³⁵ Possible roles for the *S2* and *L2* gene segments in IFN induction are unclear. The sensitivity of reovirus to the antiviral effects of IFN is also strain dependent. Reovirus T3D is more sensitive than T1L to the antiviral effects of IFN^{242,452}; this phenotype also segregates with the *M1*, *S2*, and *L2* gene segments.⁴⁵² It is possible that μ2 modulates RNA-mediated activation of antiviral ISGs as a consequence of its capacity to bind RNA.⁶³ However, it is more likely that by repressing IFN signaling μ2 allows the virus to evade the effects of IFN.

The reovirus *S4*-encoded σ3 protein binds dsRNA^{135,328,368,432,511} and can modulate the type I IFN response.⁴⁷ Several antiviral ISGs are activated either directly or indirectly by dsRNA. For example, dsRNA binds to and activates protein kinase R (PKR), which phosphorylates and inactivates eukaryotic

translation initiation factor eIF2 α , thereby inhibiting translation and potentially viral replication. Although there is no direct evidence that $\sigma 3$ blocks reovirus dsRNA induction of IFN during infection, multiple lines of evidence suggest that this is likely the case. The reovirus $\sigma 3$ protein prevents dsRNA-mediated activation of PKR *in vitro*²³⁴ and in cells.⁵⁴³ Moreover, $\sigma 3$ can substitute for analogous dsRNA-binding proteins or repressors of PKR in other viruses.^{32,181,290} PKR is activated by reovirus in IFN-treated cells²⁰⁵ and is required to protect mice against reovirus-induced disease.⁴⁷³ However, activation of PKR does not inhibit reovirus replication or limit its cytopathic effect.⁵⁴⁸ In fact, reovirus may actually benefit from PKR activation.⁴⁶² Viral dsRNA also binds to and activates 2',5'-oligoadenylate synthetase, whose products then activate the ssRNA endonuclease RNase L, another antiviral ISG. Reovirus activates RNase L in IFN-treated cells,³⁵⁶ and RNase L can cleave reovirus mRNA *in vitro*.²³ However, paradoxically, RNase L does not inhibit reovirus replication or cell damage and, as is the case for PKR, some reovirus strains produce lower titers in cells that lack RNase L.⁴⁶²

Inhibition of Cellular RNA and Protein Synthesis and Induction of Cellular Stress Responses

Some strains of reovirus inhibit the synthesis of cellular RNA and protein. The mechanism by which reovirus modulates host-cell RNA and protein synthesis is not known, but viral replication is required. Differences in the capacity of reovirus strains to inhibit cellular RNA and protein synthesis segregate with the $\sigma 3$ -encoding S4 gene segment.⁴⁴⁰ Reovirus inhibition of protein synthesis involves both PKR and RNase L and likely other IFN-stimulated gene products.⁴⁶² Virus strain-specific differences in inhibition of cellular protein synthesis⁴⁴⁰ likely reflect the capacity of the $\sigma 3$ protein to repress dsRNA-mediated activation of PKR.^{234,290,355,543} The $\sigma 3$ protein is incapable of binding dsRNA when it assembles into heterohexameric complexes with the $\mu 1$ protein during capsid morphogenesis.^{47,289,368,433,447,543} Thus, strain-specific differences in the efficiency of assembly of $\mu 1$: $\sigma 3$ complexes could determine the bioavailability of $\sigma 3$ conformers capable of binding dsRNA. Ectopically expressed $\sigma 3$ is distributed in the nucleus and cytoplasm. The subcellular distribution of $\sigma 3$ in infected cells correlates with the capacity of different strains to inhibit cellular protein synthesis.^{433,544} One attractive hypothesis is that $\sigma 3$ modulation of PKR activity and inhibition of cellular protein synthesis is determined by differences in the subcellular distribution of free $\sigma 3$, which is in turn determined by the kinetics of assembly of $\mu 1$: $\sigma 3$ complexes. Accordingly, protein synthesis inhibition may be restricted by subcellular localization of free $\sigma 3$.⁴³³

In addition to inhibition of cellular protein synthesis, the preferential translation of reovirus mRNAs likely requires other as yet unidentified mechanisms. In some infected cells, reovirus transcripts produced later in infection lack 5' caps (see Replication—Translation and Viral Factory Formation). However, it is not clear whether the absence of caps functions in the preferential translation of reovirus transcripts. Reovirus infection induces the formation of stress granules,^{383,384,461} which are discrete cytoplasmic structures that sequester mRNAs and prevent their translation. Reovirus induces stress granules early in infection using a mechanism that is dependent on phosphorylation of eIF2 α .³⁸⁴ Later in infection, stress granules in infected cells are disrupted by a mechanism independent of PKR and eIF2 α phosphorylation status and which correlates with the release

of viral mRNAs from translational inhibition.³⁸³ Under conditions in which eIF2 α is phosphorylated and concentrations of ternary complexes required for translational initiation are limited, it is likely that the preferential translation of reovirus mRNAs requires other mechanisms. However, the dissolution of stress granules may be necessary for efficient translation of viral mRNAs.

Inhibition of Cellular DNA Synthesis and Cell-Cycle Progression

Some reovirus strains inhibit cellular DNA synthesis, which is noted by 8 hours postinfection.¹⁹⁶ Early studies showed that UV-inactivated virus⁴⁴⁵ but not empty virus particles²⁷³ inhibits cellular DNA synthesis, suggesting that virion-associated RNA but not viral transcription is required for cellular DNA synthesis inhibition. However, expression of nonstructural protein $\sigma 1s$ is required for cell-cycle arrest at the G₂/M checkpoint, raising the possibility that the UV treatment used in the initial experiments may have been insufficient to completely shut-down viral transcription. Differences in the capacity of strains T1L and T3D to inhibit cellular DNA synthesis segregate with the S1 gene segment,⁴³⁹ which encodes the $\sigma 1$ and $\sigma 1s$ proteins. Purified $\sigma 1$ can arrest G₁-to-S progression, presumably by transducing signals following ligation of cell-surface receptors.⁴²⁸ Strain-specific differences in G₂/M arrest similarly segregate with the S1 gene segment.³⁸⁰ However, $\sigma 1s$ rather than $\sigma 1$ stimulates the inhibitory hyperphosphorylation of cell cycle control kinase p34 (cdc2) to bring about G₂/M arrest.³⁷⁹ Reovirus-induced G₂/M arrest also may reflect modulation of the mitotic spindle checkpoint as a consequence of virus association with microtubules and disruption of their association with the kinetochore.¹¹⁸ Analysis of strain-specific differences in reovirus-induced cellular gene expression by transcriptional profiling identified several genes that may be involved in reovirus modulation of G₁-to-S, G₂-to-M, and the mitotic spindle checkpoint.³⁷⁸ The benefit of blocking cell-cycle progression for reovirus replication is not known.

Induction of Apoptosis and Activation of NF- κ B

Apoptosis induced by reovirus is a major pathogenic mechanism underlying disease in infected mice (see Tissue Damage and Disease). Reovirus infection leads to apoptosis in many cell lines^{102,112,403,500} and primary cultures of differentiated cells.^{131,396} However, there is frequently little correlation between apoptosis induction and yield of progeny virus.^{131,403,500} Many studies of apoptosis induced by reovirus assessed viral yield by artificially lysing infected cultures, perhaps obscuring a role for apoptosis in facilitating release. Indeed, when assessed directly, apoptosis facilitates release from Ras-transformed cells,³⁰⁷ suggesting a possible function for apoptosis in the reovirus replication cycle.

Reovirus strains vary in the capacity to induce apoptosis in cell lines and primary cultures. For example, strains T3A and T3D induce significantly higher levels of apoptosis than does T1L; this difference segregates with the S1 and M2 gene segments.^{403,500,501} A variant virus that fails to express the S1-encoded $\sigma 1s$ protein induces apoptosis, implicating $\sigma 1$ in the cell-death response.⁴⁰⁴ However, $\sigma 1s$ appears to function in reovirus-induced apoptosis in the murine brain and heart,²²⁷ suggesting that there may be cell type-specific requirements for the S1 gene products in evoking cell death. Reovirus induces apoptosis in ribavirin-treated cells,¹¹¹ and UV-inactivated

virus⁵⁰⁰ and empty particles¹¹¹ induce apoptosis, demonstrating that neither viral RNA synthesis nor virion genomic dsRNA are required for apoptosis, at least in some contexts. Together, these data suggest that attachment, disassembly, and penetration are important steps in cell-death induction by reovirus.

The S1-encoded $\sigma 1$ protein of some reovirus strains binds to sialic acid as a first step in cell engagement,²⁶ which is followed by subsequent binding to JAM-A²⁷ (see Replication-Attachment). For at least some of these strains, sialic acid binding is required for inducing maximum levels of apoptosis.¹¹⁰ Regardless of sialic acid-binding capacity, reovirus binding to JAM-A is required for apoptosis during infection.²⁷ However, uptake of antibody-coated reovirus into cells expressing Fc receptors leads to apoptosis, demonstrating that JAM-A signaling is not required for this form of cell death.¹²² These observations suggest that $\sigma 1$ functions in reovirus-induced apoptosis by providing strong cell binding or routing the virus to an endocytic compartment where apoptotic signaling is initiated.

Apoptosis induced by reovirus virions is blocked by drugs that inhibit acid-dependent proteolytic disassembly, an effect that can be bypassed by *in vitro*-generated ISVPs.¹¹¹ These findings indicate that apoptosis induction requires virion-to-ISVP disassembly. Membrane penetration by the reovirus disassembly intermediate also is required for apoptosis.¹²³ However, membrane penetration likely serves primarily to deliver the $\mu 1$ effectors of apoptosis to the cytoplasm. Indeed, a mutation in the ϕ domain of $\mu 1$ that does not affect membrane penetration decreases the strength of the proapoptotic signal, indicating that the ϕ domain of $\mu 1$ regulates apoptosis following penetration.¹²¹ Concordantly, plasmid-based expression of the $\mu 1$ ϕ domain is sufficient to induce apoptosis.¹⁰⁷

Apoptosis can be elicited by mitochondrial damage via the intrinsic pathway or activation of death receptors via the extrinsic pathway. In many cell types, reovirus infection activates both intrinsic and extrinsic apoptotic pathways (Fig. 44.14), although in some cell types, one mechanism may predominate.¹³⁰ The intrinsic apoptotic pathway requires activation of pro-apoptotic Bcl-2 family members Bak and Bax, which induce permeabilization of the outer mitochondrial membrane, resulting in release into the cytosol of cytochrome *c* and Smac/DIABLO. Cytochrome *c* couples with dATP in the cytosol to trigger oligomerization of Apaf-1 to form a complex called the apoptosome, which recruits and activates caspase 9. Caspase-9 can subsequently proteolytically process and activate effector caspases 3 and 7. Smac/DIABLO represses inhibitor of apoptosis proteins (IAPs), which prevent activation of effector caspases. The extrinsic pathway is stimulated by ligand binding to cell-surface death receptors. Death receptor oligomerization following ligand binding leads to recruitment of adaptor proteins (such as FADD) that form the death-inducing signaling complex (DISC). Once formed, the DISC leads to activation of initiator caspase 8, which in turn activates effector caspases 3 and 7. In some cells, activated caspase-8 also activates the intrinsic pathway by cleaving pro-apoptotic Bcl-2 family member Bid to form a truncated version of the molecule, called tBid, which associates with the outer mitochondrial membrane and stimulates oligomerization of Bak and Bax.

Reovirus infection induces the release of cytochrome *c* and Smac/DIABLO,²⁶⁶ indicating intrinsic pathway activation. Moreover, overexpression of the antiapoptotic mitochondrial protein Bcl-2 blocks reovirus-induced apoptosis.^{265,403} Reovirus infection also induces expression of TRAIL (a death receptor

ligand) and DR5, a TRAIL receptor,¹⁰² indicating extrinsic pathway activation. Treatment of cells with soluble TRAIL receptor or overexpression of a dominant-negative form of the adaptor protein FADD inhibits reovirus-induced apoptosis.^{102,265} However, activation of the extrinsic pathway alone is insufficient for induction of apoptosis during reovirus infection and must be accompanied by activation of the intrinsic pathway to elicit a full response.^{124,265}

The $\mu 1$ ϕ domain associates with the endoplasmic reticulum and mitochondria and can induce apoptosis in the absence of reovirus infection.¹⁰⁷ Apoptosis induced by either $\mu 1$ or reovirus infection occurs in cells lacking Bak and Bax, suggesting that in the presence of $\mu 1$, tBid is sufficient to disrupt mitochondrial membranes.⁵³³ Interestingly, a peptide corresponding to the minimal region of ϕ responsible for apoptosis can autonomously destabilize membranes,²⁵⁷ raising the possibility that ϕ together with tBid directly mediates mitochondrial release of pro-apoptotic factors.

Reovirus-induced apoptosis requires the activation of NF- κ B in most cell types¹¹² (Fig. 44.14). Interestingly, reovirus strains that induce apoptosis efficiently (e.g., T3A) and poorly (e.g., T1L) activate NF- κ B early in infection, but efficiently apoptotic strains inhibit NF- κ B activation late in infection,¹⁰¹ at least in some cells. Moreover, a poorly apoptotic strain (T1L) can induce apoptosis efficiently when NF- κ B is inhibited late in infection.¹⁰³ Inhibition of NF- κ B late in infection sensitizes cells to TRAIL-mediated apoptosis, linking NF- κ B activation to the extrinsic pathway of apoptosis induction.¹⁰³ Additionally, NF- κ B-induced expression of cFLIP, which inhibits caspase 8 activity, parallels reovirus early stimulation and late inhibition of NF- κ B activation and attenuates apoptosis induced by T1L.¹⁰¹ However, NF- κ B also is required for reovirus-induced cleavage of Bid, which provides a plausible mechanism to connect NF- κ B activation to the intrinsic pathway for reovirus-induced apoptosis.¹²⁴ Reovirus activation of NF- κ B also likely regulates other events in both the extrinsic and intrinsic pathways.^{129,364}

The mechanism by which reovirus activates NF- κ B is likely dependent on virus strain and cell type. In unstimulated cells, NF- κ B is sequestered in the cytoplasm by one of several isoforms of the repressor I κ B. Following stimulation of the classical pathway of NF- κ B activation, the heterotrimeric I κ B kinase (IKK) complex, which is composed of IKK α , IKK β , and IKK γ (Nemo), phosphorylates I κ B α , leading to its ubiquitylation and degradation for release of active NF- κ B.⁴⁸¹ Following stimulation of the alternative pathway of NF- κ B activation, a complex composed of IKK α and NIK phosphorylate an NF- κ B latent component, p100, resulting in its cleavage to the activated NF- κ B moiety p52.⁴⁸¹ Expression of dominant-negative forms of I κ B inhibit NF- κ B activation and apoptosis induced by reovirus,^{103,112} suggesting stimulation of the classical NF- κ B activation pathway. However, reovirus-induced NF- κ B activation and apoptosis require IKK α and IKK γ /Nemo and not the third component of the classical pathway, IKK β ,²⁰⁹ suggesting a novel mechanism for regulation of NF- κ B by reovirus. The ϕ domain of $\mu 1$ is thought to play a role in the activation of NF- κ B, as recombinant viruses with mutations in ϕ (K594D and I595K) have reduced capacity to activate NF- κ B.¹²¹ These mutant viruses are also deficient in apoptosis induction. The mechanism by which the $\mu 1$ ϕ domain activates NF- κ B is unknown.

In contrast to most cells, reovirus-induced apoptosis in cardiac myocytes does not require NF- κ B. Levels of apoptosis

FIGURE 44.14. Reovirus activates both intrinsic and extrinsic apoptotic pathways. Reovirus-induced apoptosis requires disassembly of virions to infectious subviral particles, which leads to release of the $\mu 1$ ϕ fragment. The ϕ fragment may associate with tBid to permeabilize mitochondria. Reovirus stimulates mitochondrial release of cytochrome *c* and Smac/DIABLO, which together activate caspase 9 as part of the intrinsic apoptotic pathway. However, activation of caspase 9 is not required for apoptosis induced by reovirus infection. Instead, the critical event may be release of Smac/DIABLO to repress IAP inhibition of caspase 3. Reovirus activates IPS-1 and IRF3 as well as NF- κ B, resulting in induction of the proapoptotic protein, NOXA, which can inhibit antiapoptotic Bcl-2 family members. The $\mu 1$ ϕ fragment and other reovirus components can activate NF- κ B. Reovirus also induces expression of DR5 and TRAIL, which together activate caspase 8 as part of the extrinsic apoptotic pathway. Reovirus activation of NF- κ B is required for cleavage of Bid. Known stimulatory pathways are indicated by dark blue arrows (light blue arrows if not required); known inhibitory pathways are indicated by red bars. Possible stimulatory pathways are indicated by dashed blue arrows or question marks.

induced by reovirus strains T1L and 8B increase in primary cultures of cardiac myocytes when NF- κ B is inhibited.¹⁰¹ This increase likely reflects a requirement for NF- κ B in the induction of the antiviral cytokine IFN- β by reovirus. Similarly, apoptosis induced by reovirus strain T3SA+ increases in the heart of NF- κ B p50-null mice relative to wild-type mice.³⁶³ This effect can be ameliorated by treatment of infected animals with IFN- β .³⁶³ However, apoptosis induced by T3SA+ is decreased in the brain of NF- κ B p50-null mice, indicating that the role of NF- κ B in reovirus-induced apoptosis *in vivo* is tissue specific.³⁶³

Reovirus-induced apoptosis is regulated by additional cellular factors. Reovirus stimulates MEKK1 to activate c-Jun N-terminal kinase (JNK), resulting in phosphorylation and activation of transcription factor c-Jun.^{104,105} JNK activation is

required for efficient release of pro-apoptotic factors cytochrome *c* and Smac/DIABLO from mitochondria. Inhibitors of JNK block reovirus-induced apoptosis at low MOI and significantly delay the onset of apoptosis at high MOI.¹⁰⁴ However, the c-Jun transcription factor is not required for reovirus-induced apoptosis, indicating that JNK functions to induce apoptosis independent of its role in transcriptional activation of c-Jun. Activated JNK can directly modulate the activities of mitochondrial pro-apoptotic and antiapoptotic proteins such as Bad, Bid, and Bim.¹⁴² Thus, JNK may directly influence intrinsic apoptotic pathway activation in reovirus-infected cells. Reovirus also stimulates the innate immune response sensor IPS-1 for activation of transcription factor IRF3; these signaling events are required for induction of maximum levels of apoptosis.²²⁵ IRF3 and NF- κ B, independently of IFN- β , induce Noxa, a proapoptotic

BH3-only-domain Bcl-2 family protein; Noxa expression markedly enhances reovirus-induced apoptosis.²⁶⁰ Reovirus activates the cellular protease calpain, and apoptosis is reduced by a calpain inhibitor.¹³² Finally, reovirus stimulates TGF- β signaling, and inhibition of this pathway reduces apoptosis.³⁶ These pathways also are modulated *in vivo*.

PATHOGENESIS AND IMMUNITY

Reovirus pathogenesis and host immune responses have been studied most extensively using neonatal mice (Fig. 44.15). These studies provide most of the information in this section.

FIGURE 44.15. Viral and host factors determine reovirus tissue tropism. **Intestine.** Reovirus replication in the intestine requires conversion of virions to infectious subviral particles (ISVPs), which is catalyzed by intestinal proteases. ISVPs can infect epithelial cells at the villus tips or transit through M cells to underlying Peyer patches to infect epithelial cells in the villus crypts. Virus can spread systemically by hematogenous or neural routes from Peyer patch cells. Strain-specific differences in reovirus replication in the intestine segregate with the S1 and L2 genes. Virus-induced type I interferon (IFN) is essential for protection of intestinal tissue against reovirus infection. **Lung.** Reovirus replication in the lung also requires virion-to-ISVP disassembly, which is catalyzed by airway-resident proteases. Following transport through M cells to underlying bronchus-associated lymphoid tissue, virus infects epithelial cells basally and is released apically. Virus-stimulated T cells induce epithelial cell apoptosis and fibrosis, resulting in either bronchiolitis obliterans organizing pneumonia (BOOP) or acute respiratory distress syndrome (ARDS). **Heart.** Some reovirus strains infect and damage cardiac myocytes, leading to myocarditis. Strain-specific polymorphisms in the M1 gene segment lead to differences in virus induction of, and sensitivity to, type I IFN, which consequently influence the capacity of reovirus to cause myocarditis. Cardiac myocytes synthesize high levels of IFN, while cardiac fibroblasts synthesize high levels of antiviral IFN-stimulated genes (ISGs) and cytokines, offering an integrated network for organ protection. The S1, L1, and L2 genes are also determinants of strain-specific differences in myocarditic potential. **Central Nervous System (CNS).** Reovirus infects the CNS, but strains of different serotypes vary in the capacity to infect discrete populations of cells in the brain. The reovirus S1 gene segment, which encodes attachment protein $\sigma 1$ and nonstructural protein $\sigma 1s$, determines cell tropism within the CNS. The capacity of reovirus to infect ependymal cells and neurons, leading to hydrocephalus or encephalitis, respectively, is likely influenced by both $\sigma 1$ and $\sigma 1s$.

Entry into the Host

Reovirus infections in nature initiate in the enteric and respiratory tracts. Reoviruses bind to intestinal M (microfold) cells⁵³⁴ or pulmonary M cells³³⁹ in the epithelia and transit through these cells without replicating to reach underlying intestinal Peyer patches or bronchus-associated lymphoid tissue. Reovirus binding to intestinal M cells requires interactions of the $\sigma 1$ protein with glycoconjugates containing $\alpha 2,3$ -linked sialic acid.²¹⁷ However, viral replication in the intestine is not dependent on binding to sialic acid²⁸ or JAM-A.¹³ Binding to intestinal M cells by reovirus requires conversion of virions to ISVPs by intestinal proteases¹² (Fig. 44.15). Interestingly, while ISVPs are generated efficiently in the intestine,⁵⁴ proteases resident in the lung capable of converting virions to ISVPs *in vitro* do so inefficiently *in vivo*, perhaps because of protease inhibitors present at that site.³⁶² In comparison to intact virions, ISVPs inoculated perorally or intranasally lead to higher viral titers in the intestine²⁹ and the lung,³⁶² respectively. Moreover, pharmacologic inhibition of intestinal proteases blocks reovirus replication in the intestine.^{12,29} However, while proteolytic enzymes resident in host tissues facilitate infection by many reovirus strains,^{12,29,54,192,193} tissue proteases cleave the $\sigma 1$ protein of some strains, including T3D, and thereby compromise infectivity.³⁴⁹ Sequence polymorphisms that govern $\sigma 1$ cleavage offer one likely mechanism for strain-specific differences in reovirus replication in the intestine⁸⁷ (see Replication—Attachment), although polymorphisms in the L2-encoded $\lambda 2$ protein are also involved.⁵³ The L2 gene segment is similarly associated with the efficiency of reovirus shedding from the intestine and transmission to new hosts.²⁵⁴

Reovirus replicates in epithelial cells in the ileum⁴²⁰ and the respiratory tract.¹⁶⁴ One study suggests that intestinal epithelial cells in villus crypts are infected basolaterally from Peyer patches.⁴¹⁸ However, other studies indicate that virus infects intestinal epithelial cells at the villus tips^{13,56} (Fig. 44.15). Reovirus preferentially infects respiratory epithelial cells basolaterally and is released apically,¹⁶⁴ ensuring egress of virus into the environment for host-to-host dissemination.

Antibiotic treatment of mice reduces reovirus replication in the intestine, suggesting that the intestinal microbiota enhance reovirus replication.²⁷² Parallel studies with poliovirus suggest that the mechanism involves interactions of the virus with bacterial surface polysaccharides, which augment viral binding and infection of cells.²⁷²

Spread of Virus

Reovirus can disseminate from a site of entry to distant sites within the host by hematogenous or neural routes. Access to lymphoid cells in Peyer patches and bronchus-associated lymphoid tissue offers one potential mechanism for virus spread, as reovirus can bind to B and T lymphocytes.¹⁵⁹ Indeed, type 1 reoviruses access the CNS and other tissues primarily by hematogenous routes, perhaps by adhering to the lymphocyte surface,⁴⁹⁸ although these viruses can infect and replicate in sensory neurons in some circumstances.¹⁷¹ Reoviruses also can spread directly from Peyer patches to the CNS. Reovirus strain type 3 clone 9 (T3C9) transits from Peyer patches to adjacent neurons of the myenteric plexus, then through vagal autonomic nerves to the vagal dorsal motor nucleus in the brainstem.³⁴² In addition,

type 3 reoviruses can use hematogenous routes to access the CNS and other tissues.^{13,55}

Neural spread of type 3 reoviruses from the site of intramuscular inoculation to the spinal cord is inhibited by surgical transection of the sciatic nerve.^{55,498} Interestingly, sciatic nerve section delays, but does not inhibit, type 3 reovirus invasion of the brain,⁵⁵ indicating an important role for hematogenous dissemination to that site. Reovirus neural spread is diminished by colchicine, which inhibits fast axonal transport, but not by β - β' -iminodipropionitrile, which inhibits slow axonal transport.⁴⁹⁸ However, the interval between inoculation into the hind limb muscle and detection of virus in the brain is not uniformly consistent with either fast or slow axonal transport.^{55,498} Therefore, the precise mode of reovirus neural dissemination awaits further clarification.

Preference for hematogenous or neural routes of spread following intramuscular inoculation is determined by the viral S1 gene segment,⁴⁹⁸ which encodes viral attachment protein $\sigma 1$ and nonstructural protein $\sigma 1s$. The $\sigma 1$ proteins of both type 1 and type 3 reovirus strains use JAM-A as a receptor,^{27,76} which is required for infection of endothelial cells by both serotypes.¹³ Therefore, a requirement for JAM-A for reovirus infection of endothelial cells and hematogenous spread does not explain virus strain-specific differences in preference for that dissemination route. Similarly, preference for hematogenous routes by viruses with a type 1 S1 gene segment is not explained by the greater replication of T1L than T3D in cultured endothelial cells, as that capacity segregates with the T1L M1 rather than the S1 gene segment.³¹² The $\sigma 1s$ protein is required for viremia and hematogenous spread of both type 1 and type 3 reoviruses^{55,56} but dispensable for neural spread.⁵⁵ Therefore, $\sigma 1s$ polymorphisms are not likely to explain preference for hematogenous spread. Instead, it is possible that differential binding of type 1 and type 3 reoviruses to a neural receptor yet to be identified determines preference for neural spread. This idea is consistent with the observation that viral strain-specific differences in CNS tropism segregate with the S1 gene segment.⁵¹⁴ The capacity of type 3 $\sigma 1$ to bind sialic acid enhances the efficiency of viral dissemination.²⁸ However, it is not clear whether $\sigma 1$ interactions with sialylated glycans influence spread by hematogenous or neural routes.

Tissue Tropism, Damage, and Disease

Depending on the route of inoculation, reoviruses first replicate in the intestine, lung, or skeletal muscle and then spread from those primary sites to replicate in the liver, spleen, heart, brain, and other organs. Host factors required for reovirus replication influence pathogenesis. For example, reovirus intracellular disassembly is mediated by endosomal cathepsins B,¹⁵⁶ L,¹⁵⁶ or S,¹⁹¹ depending on the cell type (see Replication—Disassembly). In comparison to wild-type mice, peak reovirus titers in cathepsin B-null mice following peroral inoculation are similar in the intestine but lower in the heart and brain.²⁴⁷ Accordingly, survival of reovirus-infected cathepsin B-null mice is prolonged and mortality decreased,²⁴⁷ consistent with tissue-specific augmentation of viral replication by cathepsin B. Similarly, compared with wild-type mice, peak reovirus titers in perorally inoculated mice lacking cathepsins L or S also are diminished at sites of secondary replication.²⁴⁷ However, while survival is prolonged, mortality in these animals is increased,²⁴⁷ consistent with a defect in cell-mediated immunity in mice

deficient in either of these enzymes.⁸⁶ Treatment of infected mice with a cathepsin L inhibitor decreases viral titers and increases survival,²⁴⁷ suggesting that transient abrogation of cathepsin L activity can inhibit viral replication with minimal compromise of cell-mediated immunity.

Central Nervous System

Type 1 reoviruses infect the ependymal cells lining the ventricles in neonatal mice, which results in ependymitis and hydrocephalus.⁵¹⁵ In contrast, type 3 reoviruses infect neurons in these animals, replicate to high titers in the brain, and induce a lethal meningoencephalitis.⁵¹⁵ Type 3 reoviruses also damage spinal cord neurons resulting in acute flaccid paralysis.²⁰¹ The capacity to infect ependymal cells⁴⁸⁴ or neurons¹⁴³ and the resulting disease phenotypes⁵¹⁴ are determined by the S1 gene segment (Fig. 44.15). S1-determined differences in infection of ependymal cells correlate with differences in virus attachment to these cells,⁴⁸⁴ implicating $\sigma 1$ rather than $\sigma 1s$ in this tropism difference. However, analogous binding studies using primary cultures of neurons have not been reported. Infection of neurons in the brain does not require JAM-A¹³ or sialic acid,²⁸ and the viral receptor on those cells remains unidentified. The $\sigma 1s$ protein is dispensable for reovirus replication in the brain,^{56,227} but it influences apoptosis and tissue damage in that organ.²²⁷ Therefore, it is likely that both $\sigma 1$ and $\sigma 1s$ contribute to S1-determined differences in reovirus-induced CNS disease.

Type 3 reovirus field-isolate strains differ in virulence and peak titers achieved in the brain, but they induce similar patterns of tissue damage.²²⁸ However, variants of T3D selected for resistance to $\sigma 1$ -specific monoclonal antibodies are attenuated.^{398,467} One particularly well-studied variant, variant K, produces peak titers and cell damage in the hippocampus comparable to T3D. However, unlike T3D, this variant produces 1,000-fold lower titers and induces minimal neuronal damage in the cortex, patterns that are reproduced in primary cultures of hippocampal and cortical neurons.³⁹⁸ Variant K differs from T3D by a single amino acid substitution in the globular head of $\sigma 1$ ³⁰ (see Replication–Attachment), but the mechanism of differential replication and damage in the brain is not known.

Type 3 reoviruses induce apoptosis in neuronal cultures and in the brain.^{35,123,124,199,200,227,365,396,397–398} Cell killing by apoptosis plays a critical role in reovirus-induced CNS disease. A reovirus mutant with a single amino acid substitution in the ϕ domain of the M2-encoded $\mu 1$ protein does not affect membrane penetration but does diminish pro-apoptotic signaling.¹²¹ This mutant is less neurovirulent compared with wild-type virus,¹²¹ which provides one possible explanation for the genetic association of the reovirus M2 gene segment with neurovirulence.²²⁸ Although the majority of apoptotic cells in the CNS are infected, suggesting direct effects of the virus, nearby uninfected apoptotic cells suggest the existence of additional “bystander” mechanisms of cell death.^{365,396}

Reovirus-induced apoptosis involves both extrinsic and intrinsic pathways (see Responses of the Host Cell to Infection—Induction of Apoptosis and Activation of NF- κ B). Reovirus activates NF- κ B in the brain, and apoptosis is significantly diminished in the CNS of NF- κ B p50-null mice.³⁶³ Activation of NF- κ B is required for reovirus-induced cleavage and activation of the proapoptotic protein, Bid; reovirus replication and

histopathologic injury in the brain are substantially reduced in Bid-deficient mice.¹²⁴ Additionally, reovirus-induced apoptosis, but not viral replication, is diminished in the CNS of mice lacking the proapoptotic Bcl-2 protein, Bax.⁴⁵ Reovirus replication, CNS injury, and spread within the CNS are also reduced and survival enhanced in mice lacking effector caspase 3.³⁷ Reovirus also activates JNK, which upregulates Fas, and chemical inhibitors of JNK attenuate reovirus-induced encephalitis.^{35,100}

Reoviruses induce multiple protective responses in the CNS. Gene expression associated with IFN signaling is induced early in infection, but reovirus stimulates other cytokines and apoptotic pathways later in infection.⁴⁹⁶ Experiments using brain-slice cultures also indicate that reovirus induces cytokines and apoptotic pathways in neural tissues.¹⁴⁴ Reovirus activates the JAK-STAT pathway in the brain,¹⁹⁹ and when type I IFN signaling is ablated, reovirus tropism in the brain is extended to new neuronal populations with a concomitant increase in lethality.^{144,199} Interestingly, neurons in which STAT1 is activated are often uninfected,¹⁹⁹ suggesting that reovirus infection is prevented by IFN-mediated antiviral effects and consistent with reovirus repression of IFN signaling in infected cells.^{235,556} Reovirus also increases nitric oxide (NO) production and expression of inducible nitric oxide synthase (iNOS) in primary mouse cortical neuron cultures and brains of infected mice.²⁰⁰ Inhibition of iNOS increases reovirus replication in neurons, while an NO donor decreases reovirus replication in these cells.²⁰⁰

Following infection of the brain, reovirus activates TGF- β receptor I and its signaling effector SMAD3 as well as another member of the TGF- β superfamily, bone morphogenetic protein (BMP) receptor I, and its effector SMAD1.³⁶ Inhibition of TGF- β signaling *in vivo* decreases SMAD3 activation and increases reovirus-induced apoptosis.³⁶ Similarly, inhibition of BMP signaling in primary mouse cortical neuron cultures decreases SMAD1 activation and increases neuronal apoptosis, while viral replication remains unchanged. Treatment with a BMP agonist has the opposite protective effect.³⁶ Interestingly, SMAD1 activation occurs predominantly in adjacent uninfected neurons,³⁶ similar to the pattern observed for the activation of STAT1.¹⁹⁹ Thus, reovirus appears to selectively suppress protective responses in infected neurons.

Heart

Reovirus-induced cardiac damage in neonatal mice is caused by a direct cytopathic effect on cardiac cells^{31,450,451} (Fig. 44.15). Focal lesions are evident throughout the endocardium, myocardium, and epicardium, associated with cardiac myocyte loss and visible dystrophic calcification on the surface of the heart in the absence of significant inflammatory infiltrate.⁴⁵¹ Reovirus myocarditis is not immune mediated, as reovirus infection causes myocarditis in nude mice, which lack T cells,⁴⁵¹ and in severe combined immunodeficiency (SCID) mice, which lack both B and T cells.⁴⁵⁰ The capacity to induce myocarditis is virus strain specific. Studies of reoviruses that vary in myocarditic potential indicate that the extent of myocardial damage correlates with cytopathic effect in primary cultures of cardiac myocytes.³¹ A protease inhibitor that blocks reovirus replication at an early step inhibits reovirus-induced myocarditis, indicating that viral replication is required for disease.²⁵⁸ Interestingly, reoviruses that fail to induce myocarditis in immunocompetent mice also fail to do so in SCID mice,⁴⁵⁰ providing

additional evidence that development of cardiac lesions is not determined by the adaptive immune response but instead reflects virus interactions with cardiac cells.

The type I IFN response regulates reovirus-induced myocarditis. The capacity of reovirus strains to induce myocarditis correlates inversely with induction of and sensitivity to type I IFN in cardiac myocytes.⁴⁵² Moreover, nonmyocarditic reovirus strains induce cardiac lesions in mice when IFN induction^{224,363,452} or IFN-induced gene expression^{20,473} is inhibited. Myocarditic capacity segregates primarily with the reovirus M1 gene segment but also is influenced by the S1, L1, and L2 gene segments.^{448,449} The M1 gene segment determines reovirus strain-specific differences in replication in cardiac myocytes,³¹³ and nonmyocarditic reovirus strains achieve titers comparable to those of myocarditic reoviruses in cardiac myocytes when the IFN response is inhibited.^{235,452} The M1-encoded $\mu 2$ protein can repress IFN signaling,⁵⁵⁶ a property determined by a single sequence polymorphism in $\mu 2$ at amino acid 208²³⁵ (see Responses of the Host Cell to Infection—Interferon Induction and Effects on Viral Replication). Substitution at that position modulates reovirus induction of IFN, replication in cardiac myocytes, and myocardial injury, although other reovirus determinants also influence these properties.²³⁵ Therefore, the strength of the IFN response and viral subversion of IFN effects are critical determinants of virus strain-specific differences in damage to the heart.

The potentially myocarditic reovirus strain 8B induces apoptosis in primary cultures of cardiac myocytes,^{101,128,130,131,333} suggesting a link between apoptosis and myocardial injury. Concordantly, reovirus strain-specific differences in induction of apoptosis in primary cardiac myocyte cultures correlate with the capacity to induce myocarditis.³³³ Myocarditic reovirus strains activate caspase 8, which is associated with the death receptor-initiated extrinsic apoptotic pathway, and caspase 3, an effector caspase, in primary cultures of cardiac myocytes and in the heart.¹³⁰ In contrast, caspase 9, which is associated with the intrinsic mitochondrial apoptotic pathway, is only weakly activated, and the mitochondrial transmembrane potential is unaltered.¹³⁰ Pretreatment of neonatal mice with calpain or caspase inhibitors dramatically reduces cardiac damage caused by potentially myocarditic reovirus strains.^{128,131} Finally, as is the case in the CNS, the $\sigma 1$ s protein is dispensable for reovirus replication in the heart, but it influences apoptosis and tissue damage in that organ.²²⁷ Thus, death of cardiac myocytes during reovirus-induced myocarditis appears to occur as a consequence of apoptosis.

Patterns of reovirus-induced gene expression in the heart vary according to virus strain and cardiac cell type. The capacity to induce cardiac lesions correlates with cytopathic effect in primary cultures of cardiac myocytes but not cardiac fibroblasts.³¹ Indeed, myocarditic reovirus strains preferentially induce apoptosis of cardiac myocytes relative to cardiac fibroblasts, while nonmyocarditic reoviruses induce the converse.³³³ Nonmyocarditic reoviruses also induce expression of cytokines in cardiac fibroblasts that likely contribute to disease outcome *in vivo*.³³³ Reovirus induction of type I IFN and ISG expression also differs between cardiac myocytes and cardiac fibroblasts^{288,474,555} (Fig. 44.15). In keeping with the differences in gene expression, reovirus-induced changes in the cardiac myocyte proteome also differ between virus strains and correlate with the capacity to induce myocarditis.²⁸⁷ Thus, reovirus

cardiac damage reflects an array of host responses determined by both viral and cardiac cell factors.

Hepatobiliary System and Diabetes

Neonatal mice infected with some type 3 reovirus strains develop oily fur syndrome, appearing as though they have been dipped in oil.^{28,140,530} This syndrome is associated with viral replication in intrahepatic bile duct epithelium, leading to biliary obstruction and fat malabsorption, which mimic in some respects human infantile biliary atresia. Differences in the capacity of reovirus strains to induce oily fur syndrome segregate with the S1 gene segment.⁵³⁰ A sialic acid-binding reovirus strain (T3SA+), but not a congenic strain that does not bind sialic acid (T3SA-), infects bile duct epithelial cells following peroral inoculation and induces periportal inflammation and bile duct necrosis, resulting in oily fur syndrome.²⁸ Moreover, T3SA+ but not T3SA- binds a human biliary epithelial cell line *in vitro*. Thus, reovirus binding to sialic acid is required for biliary tract destruction and oily fur syndrome.²⁸ Mutations in the M2 gene segment can abrogate the capacity to induce this disease, although the mechanism underlying this effect is unclear.¹⁴⁰

Nonobese diabetic (NOD) mice provide a model system for investigation of type I diabetes mellitus, an autoimmune disease resulting from destruction of pancreatic β cells. Following inoculation of neonatal NOD mice, reovirus strain T3A infects pancreatic islet cells, which prevents the development of diabetes but not the insulinitis (the recruitment of CD8+ T cells and macrophages to pancreatic islets by autoreactive CD4+ T cells).⁵²³ These findings suggest that T3A-induced cytopathic effect and release of antigens from β cells leads to tolerance by induction of regulatory T cells, thereby delaying the onset of diabetes.

Lung

Reovirus strain T1L inoculated intranasally into adult mice induces two different types of pulmonary tissue damage and fibrosis, which model distinct forms of lung disease in humans (Fig. 44.15). T1L can induce bronchiolitis obliterans organizing pneumonia (BOOP), which is characterized by inflammation and intra-alveolar fibrosis.³⁰⁰ However, when inoculated at a 10-fold higher dose, T1L induces acute respiratory distress syndrome (ARDS), which is characterized by an acute phase with severe inflammation and a chronic phase with persistent intra-alveolar and interstitial fibrosis.³⁰⁰ T1L inoculated into adult mice thymectomized as neonates induces ARDS but not BOOP, suggesting a requirement for T cells in BOOP pathogenesis.³⁰⁰ Moreover, corticosteroid treatment or depletion of CD4+ T cells, CD8+ T cells, or IFN- γ prior to inoculation inhibits the development of fibrotic lesions, consistent with a pathologic role for T cells in this disease.³⁰¹ T1L induces apoptosis of epithelial cells in both BOOP and ARDS. However, apoptosis as a direct consequence of T1L infection is unlikely to contribute to lung injury. Instead, Fas and FasL upregulated on the surface of infiltrating T cells likely mediate pulmonary epithelial cell apoptosis.²⁹² Pulmonary inflammation and fibrosis induced by T1L are diminished when caspase 8 is inhibited. However, T1L induces ARDS but not BOOP in mice expressing inactive Fas.²⁹² Thus, while apoptosis may contribute to the pathogenesis of both diseases, the Fas/FasL pathway is required only for the development of BOOP. Collectively, these

findings suggest that infiltrating T cells stimulated by reovirus T1L induce alveolar epithelial cell apoptosis and fibrosis and that apoptosis in BOOP but not ARDS is dependent on the Fas/FasL pathway.

Juvenile rats inoculated intratracheally with T1L also develop an acute pneumonia, characterized by degeneration of terminally differentiated type I alveolar epithelial cells, type II alveolar epithelial cell hyperplasia to replace the destroyed type I cells, and infiltration of leukocytes.³⁴⁰ Inoculation with T3D induces a similar pattern of pneumonia but with a more prominent neutrophil infiltrate. Both reovirus strains replicate in type I epithelial cells, but T1L achieves higher titers. The capacity to induce neutrophil infiltration segregates with the T3D S1 gene segment, while replication to high titers segregates with the T1L S1 gene segment.³⁴⁰

Reovirus infection of primary human airway epithelial cell cultures is more efficient following basolateral as opposed to apical adsorption of virus and is dependent on JAM-A.¹⁶⁴ Despite a preference for basolateral entry, reovirus is released from the apical surface of respiratory epithelial cells and does not disrupt the tight junctions.¹⁶⁴ These results suggest that epithelial cells are not the primary cell type responsible for systemic spread of reovirus from the respiratory tract to distant sites within the host.

Airway-resident proteases capable of catalyzing reovirus disassembly enhance infection in the lung. Type II transmembrane serine proteases that are expressed in human airways facilitate reovirus uncoating and infection *in vitro*. However, murine homologs of these enzymes are inefficient *in vivo*, likely reflecting repression by endogenous protease inhibitors.³⁶² Reovirus induces neutrophil infiltration in the lung,³⁴⁰ and the serine protease neutrophil elastase¹⁹³ as well as other inflammatory proteases facilitate reovirus uncoating and infection *in vitro*.³⁶² Treatment of mice with agents that induce pulmonary inflammation prior to intranasal inoculation of reovirus increases conversion of virions to ISVPs and enhances viral replication in the lung,³⁶² suggesting that inflammatory proteases facilitate reovirus infection at that site.

Reovirus Genetic Determinants of Tropism and Tissue Injury

Reovirus strains differ in the capacity to infect specific organs and produce tissue-specific disease in neonatal mice. Gene segments that segregate with such differences in reovirus pathogenesis have been identified in many cases (Fig. 44.15). The S1 and L2 gene segments determine the magnitude of reovirus replication in the intestine and efficiency of viral shedding in the stool. The S1 gene segment determines whether reovirus infects CNS neurons resulting in encephalitis or ependymal cells causing hydrocephalus, although the M2 gene segment influences neurovirulence. The M1 gene segment is the predominant determinant of the capacity of reovirus to cause myocarditis, although the S1, L1, and L2 gene segments influence the extent of cardiac damage.

Adult SCID mice, which lack B cells and T cells, are susceptible to reovirus infection and provide an alternative approach to identifying viral determinants of tissue tropism and disease. Results of experiments using these animals are largely consistent with those obtained in studies of neonatal mice, but they provide several additional associations between specific reovirus gene segments and infection in the intestine,

heart, and CNS.²⁰⁷ Importantly, results gathered in studies of adult SCID mice provided the first identification of reovirus genetic determinants of liver damage, which include the M1, L1, and L2 gene segments.²⁰⁷

Innate Immune Responses

Cells infected by reovirus express an array of innate protective responses, including cytokines, chemokines, and iNOS (see Responses of the Host Cell to Infection). Natural killer (NK) cells also are recruited to reovirus-infected tissues, but NK cells are neither necessary²⁴⁵ nor sufficient^{206,485} to clear the virus. Neutrophils are recruited to reovirus-infected tissues,³⁴⁰ but their importance in reovirus clearance has not been defined.

The type I IFN response is essential for protection against reovirus infection (see Responses of the Host Cell to Infection—Interferon Induction and Effects on Viral Replication). Following peroral inoculation, strain T1L induces type I IFN in Peyer patches and is cleared from the intestines of wild-type mice.²⁴⁵ In contrast, T1L damages the intestinal mucosa in IFN- α/β -receptor-null mice, depletes lymphoid cells, is not cleared, and causes a lethal outcome.²⁴⁵ The majority of T1L-induced type I IFN in Peyer patches is generated by dendritic cells (DCs). Consistent with studies implicating RIG-I and MDA-5 for reovirus induction of IFN,^{225,250,291} mice lacking TLR3 or its effector molecule MyD88 do not differ from wild-type mice in the response to T1L infection.²⁴⁵

Activation of NF- κ B by reovirus is required for the induction of IFN- β , which in turn protects against reovirus-induced encephalitis^{144,199} and myocarditis.^{224,235,363,452} However, in reovirus-infected mice, the role of NF- κ B in disease pathogenesis is organ specific. Apoptosis following reovirus infection is reduced in the brains of mice lacking the NF- κ B p50 subunit,³⁶³ consistent with a proapoptotic role for NF- κ B in reovirus infection of the CNS. In contrast, reovirus replication and apoptosis are increased in the hearts of p50-deficient mice, and these effects are prevented by treatment with IFN- β .³⁶³ These observations are consistent with NF- κ B-independent apoptosis by reovirus in cardiac myocytes¹⁰¹ and the importance of IFN- β in protection against reovirus-induced myocarditis.⁴⁵² In transformed cells, Ras enhances reovirus replication at least in part by suppressing RIG-I-mediated induction of IFN- β ⁴⁵⁴ (see Reovirus Oncolytics).

Adaptive Immune Responses

Reovirus replicates to high titers in neonatal mice, but replication in adult immunocompetent mice is modest and requires inoculation with high doses of virus.⁴²⁰ In contrast, reovirus replicates to high titers and is lethal in adult SCID mice (B cell- and T cell-deficient), and passive transfer of lymphocytes protects these animals against lethal infection.^{25,185,207,485} Together, these results suggest that the adaptive immune response influences the age-dependent restriction of reovirus replication and disease in mice. However, reovirus can induce immune cell-mediated pathology, as noted in cases of reovirus-associated lung disease.

Reovirus strains T1L and T3D do not replicate in peripheral blood mononuclear cells (PBMCs) or DCs derived from PBMCs *in vitro*,^{146,161,172} although these strains do replicate in THP-1 human monocyte cells.¹⁶⁶ Instead, DCs adsorbed with reovirus *in vitro* become loaded with viral antigen¹⁷² and express cell-surface markers and cytokine patterns characteristic of DC activation.¹⁶¹ Reovirus-exposed DCs, but not reovirus alone,

activate a majority of T cells for antigen-independent cytolytic activity and NK cells for perforin/granzyme-mediated cytotoxicity.¹⁶¹ Activation of T cells requires direct cell-to-cell contact with DCs, while activation of NK cells is mediated by DC-secreted soluble factors.¹⁶¹

The immune system of the intestine includes inductive (Peyer patches and mesenteric lymph nodes) and effector (lamina propria and intraepithelial lymphocytes [IELs]) sites. Following peroral inoculation, reovirus T1L infects epithelial cells in the intestine, resulting in activation of DCs in Peyer patches.²⁴⁵ Peyer patch DCs exposed to reovirus T1L *in vivo* can activate reovirus-primed CD4+ T cells *in vitro*¹⁷² and likely also activate T cells in the intestine. Indeed, reovirus T1L-activated T cells in Peyer patches migrate to the lamina propria and intraepithelial sites.⁵⁰ These activated T cells utilize perforin, Fas-FasL, and TRAIL pathways for cytotoxicity, but pathway preference is dependent on the mucosal site from which the T cells are harvested.⁵⁰ IELs induced by T1L express the $\alpha\beta$ T-cell receptor (TCR) and CD4, CD8, or both CD4 and CD8, and express IFN- γ characteristic of activated effector cells.⁴⁹ Depletion experiments indicate that CD8+Thy-1+ T cells expressing the $\alpha\beta$ TCR mediate IEL CTL activity.¹¹⁷

The humoral immune response to reovirus is important in protection of the intestine, mediating clearance following primary infection and prevention of secondary infection. Reovirus is cleared from the intestines of adult wild-type and $\beta 2$ microglobulin-null (CD8+ T cell-deficient) mice but not SCID (B cell- and T cell-deficient) and MuMT (B cell- and antibody-deficient) mice.^{25,185,207,303,485} Reovirus T1L inoculated perorally into adult mice induces intestinal IgA and serum IgG.⁴⁵⁷ Viable or UV-inactivated reovirus T3D induces polymeric immunoglobulin receptor expression in H29 human intestinal epithelial cells,³⁷¹ suggesting a possible mechanism for intestinal IgA secretion. During primary infection, reovirus T1L is cleared equally well from the intestines of IgA-null mice and wild-type mice. However, following subsequent challenge, reovirus T1L invades Peyer patches of IgA-null but not wild-type animals,⁴⁵⁷ consistent with a protective role for IgA during reinfection.

Studies using exogenous effectors offer additional insights into the importance of antibodies in protection of the intestine against reovirus infection. Oral introduction of IgA or IgG specific for the $\sigma 1$ protein protects Peyer patches from infection by reovirus T1L.^{232,457} Adoptive transfer of splenic lymphocytes derived from reovirus-immune mice inhibits reovirus strain T3C9 replication in the intestine, but efficacy is diminished if B cells are depleted prior to transfer, indicating that antibody responses are important.²⁵ Intraperitoneal introduction of reovirus-specific polyclonal antiserum or IgG2a monoclonal antibody into MuMT mice leads to clearance of T3C9.²⁵

Antibody and immune cells protect against reovirus infection at distinct stages of the virus-host encounter. Following systemic administration, neutralizing monoclonal antibodies specific for the $\sigma 1$ protein do not inhibit primary replication of reovirus T3C9 in the intestine or T3D in skeletal muscle. However, these antibodies potentially inhibit viral spread from both of those sites to the spinal cord.⁵⁰² Even when administered after virus has reached the spinal cord, antibody prevents viral spread to the brain. Antibody also inhibits replication in the brain following intracranial inoculation of T3D^{502,508} and spread from the brain to the eye, spinal cord, and muscle.⁵⁰²

Similarly, monoclonal antibodies that do not inhibit T1L replication in skeletal muscle inhibit viremia and replication in the brain.⁴⁹⁷ Together, these results indicate that antibody can mediate protection by blocking steps in viral pathogenesis following primary replication.

Adoptive transfer of adult spleen cells protects neonatal mice from T3C9 inoculated perorally, T3D inoculated parenterally, and T1L (but not T3D) inoculated intracranially.⁵⁰⁹ Depletion of either CD4+ or CD8+ T cells leads to significantly increased replication of both T3C9 and T3D. Adoptive transfer of immune cells is more effective than monoclonal antibodies in inhibiting viral replication, while the converse is true for inhibition of neural spread of virus.⁵⁰⁹

The route of reovirus inoculation is an important determinant of both humoral and cell-mediated immune responses. Peroral inoculation of reovirus T1L induces predominantly IgA in Peyer patches, while parenteral inoculation of that strain induces predominantly IgG2a in peripheral lymph nodes.³⁰² However, peroral inoculation of T1L induces IFN- γ and other Th1 cytokines but minimal Th2 cytokines.¹⁶⁵ Peroral inoculation of T1L also induces serum IgG2a, characteristic of a Th1 response, while parenteral inoculation induces both IgG1 and IgG2a, although this effect is MHC haplotype specific.³⁰² Finally, peroral inoculation of T1L suppresses the expression of Th2 cytokines IL-4 and IL-10 in draining lymphatic tissues early in infection, and treatment with IL-4 or IL-10 decreases serum IgG2a relative to IgG1.³¹¹ Thus, peroral inoculation of reovirus suppresses Th2 cytokines, resulting in a Th1-biased cell-mediated immune response. Concordantly, PBMCs from volunteers presumed to have been infected with reovirus in the past express recall responses when exposed to reovirus that are dominated by strong Th1-like and minimal Th2-like cytokine expression.¹⁴⁶ Interestingly, the requirements for specific PBMC subsets and ligand interactions to elicit cytokine responses are dependent on the virus strain used for stimulation.¹⁴⁶ The route of inoculation also is a determinant of TCR usage by CD8+ T cells. Inoculation of reovirus T1L perorally or parenterally induces preferential usage of TCR variable gene segment V $\beta 6$. However, peroral inoculation additionally restricts TCR β gene segment usage, suggesting an even greater limitation on TCR specificity.¹⁷⁵

EPIDEMIOLOGY AND HOST RANGE

Epidemiology

Epidemiologic surveys for the presence of reovirus antibodies in diverse populations suggest that most humans have been exposed to reovirus and that infection occurs early in childhood.²⁸⁵ However, reovirus infections are rarely symptomatic. In a 1994 study using ELISA to examine 850 serum samples from healthy European volunteers ranging in age from 6 months to over 60 years, the frequency of individuals with detectable IgG antibodies specific for reovirus rose with increasing age.⁴³⁷ Prevalence was approximately 35% in infants 6 months to one year, approximately 60% in individuals 11 to 19 years, and approximately 75% to 85% in individuals 20 years and older with no apparent decline after 60 years of age. In a 2005 study using ELISA to examine 272 serum samples from healthy US children ranging in age from birth to 6 years, there was rapid loss of maternal antibody as evidenced by declining seroprevalence

from 75% (6 of 8) in infants 0 to 3 months of age to 11% (1 of 9) in those from 3 to 6 months of age.⁴⁸² In contrast to results from the 1994 study, none of the 25 individuals 6 months to 1 year of age were seropositive. Seroprevalence increased in the remaining 181 individuals tested, ranging from 8% (4/49) in 1 to 2 year olds to 50% (11/22) in 5 to 6 year olds. Thus, while results from individual studies vary, reovirus infections are common before adulthood.

Host Range

Nonfusogenic mammalian orthoreoviruses infect a wide variety of species⁴¹¹ including swine^{116,411,546} and cattle.^{116,411} However, the significance of reovirus as a food animal pathogen is unclear. Reovirus infections also are common in dogs,¹³³ and reoviruses can be isolated from dogs with respiratory or enteric symptoms. However, experimental infections have not provided conclusive evidence that these viruses are pathogenic in canine species,⁷⁴ suggesting that concomitant infections with other agents are required to produce disease. Reovirus infections are common in both wild³⁷⁴ and domesticated^{116,435} cats, and reoviruses can be mildly pathogenic in experimentally infected feline species.^{335,435}

Fusogenic orthoreoviruses infect birds, mammals, and reptiles. Fusogenic bat reoviruses can be isolated from humans with clinical symptoms⁹⁶⁻⁹⁸ and, in one study, 13% of individuals frequently exposed to fruit bats were seropositive⁹⁶ (see Clinical Features—Pneumonia). Additional studies will be required to clarify the prevalence and clinical importance of these zoonotic events.

CLINICAL FEATURES

Reovirus Infections of Humans

Despite its near ubiquity, reovirus infections in humans and other animals are rarely symptomatic. When reoviruses do produce symptoms, the most common manifestations are coryza, pharyngitis, and cough²⁴⁰ as well as gastroenteritis.¹⁸⁹ Human-challenge studies conducted in the 1960s demonstrated that inoculation of reovirus strains representing each of the three serotypes by nasal instillation led to seroconversion in most cases, but only type 1 reovirus was associated with significant disease.⁴¹⁵ Three of eight previously seronegative individuals infected with type 1 reovirus developed headache, pharyngitis, sneezing, rhinorrhea, cough, and malaise. A fourth individual developed loose stools but was otherwise asymptomatic. Eight of nine individuals infected with type 3 reovirus had positive stool cultures.⁴¹⁵ One infected individual developed mild rhinitis, but the others remained well.

A large outbreak of type 1 reovirus infection was documented in institutionalized children in Washington, DC.⁴¹⁶ During a 9-week period in the months of January, February, and March, 22 of 73 children had at least one stool culture positive for type 1 reovirus. Stool shedding lasted for at least 1 week in the majority of the children. During the interval of virus isolation, the children had rhinorrhea (81%), pharyngitis (56%), diarrhea (19%), and otitis media (19%). However, the frequency and nature of these complaints did not differ significantly from those in the pre- and postisolation period. Therefore, it is not clear that the symptoms were associated with reovirus infection.

Biliary Atresia

Perhaps the strongest association of reovirus with human disease occurs in neonatal biliary atresia. This illness manifests in about 1 in 10,000 live births in the United States and is characterized by progressive inflammatory obliteration of extrahepatic and intrahepatic bile ducts.⁴⁸ Biliary atresia is thought to be precipitated by an environmental insult like a viral infection that triggers inflammatory destruction of bile duct epithelium. In a study performed in Denver, Colorado, reovirus RNA was detected by RT-PCR in fresh-frozen liver biopsy specimens in 78% (7 of 9) of tissue specimens from infants with choledochal cysts, a condition related to biliary atresia, and 55% (11 of 20) of those from infants with extrahepatic biliary atresia. However, reovirus RNA was detected in only 21% (7 of 33) of those with other liver diseases and 12% (2 of 17) of autopsy controls without known hepatic or biliary disease.⁴⁹⁹ The differences were statistically significant and support an association between reovirus infection and choledochal cysts and biliary atresia. A second study conducted in Hanover, Germany detected reovirus RNA in 33% (21 of 64) of fresh liver biopsies taken during Kasai portoenterostomy procedures.³⁹³ No other virus was detected in this study at a frequency of greater than 11%. However, other studies using different RT-PCR techniques failed to detect reovirus RNA in formalin-fixed tissue⁴⁷¹ or fecal samples.⁴²⁴ It is possible that these discordant findings are attributable to differences in the patient populations tested or dissimilar assay conditions (e.g., PCR primers and use of tissue fixatives).

Studies to examine the prevalence of reovirus-specific antibodies in infants with biliary atresia have yielded conflicting results. Some have found increased reovirus seroprevalence in such children,^{190,337,400} while others have not.^{71,72,155,331} Since reovirus infections are nearly universal by adulthood^{285,400,437,482} (see Epidemiology and Host Range), most infants will acquire reovirus-specific antibodies passively from their mothers. Therefore, it is not surprising that levels of reovirus-specific antibodies might not differ between infants with biliary atresia and healthy controls.

It is possible that only certain reovirus strains possess the appropriate combination of virulence determinants to induce biliary atresia. Following peroral inoculation of newborn mice, strain T3SA+, which binds sialic acid, causes bile duct injury. However, strain T3SA–, which does not bind sialic acid, does not harm bile ducts²⁸ (see Pathogenesis and Immunity—Hepatobiliary System). These strains also differ in the capacity to bind cholangiocarcinoma cells,²⁸ suggesting that sialic acid-binding capacity serves as a reovirus tropism determinant for biliary epithelium. It is possible that biliary atresia results only when an infant born to a reovirus antibody-negative mother is infected with a bile duct-tropic reovirus strain in the peripartum period. Additionally, a genetic predisposition toward aberrant inflammatory responses may be a prerequisite for development of the characteristic biliary fibrosis that follows viral infection.⁴⁸

Central Nervous System Disease

There are isolated case reports linking reovirus strains of all three serotypes to neurologic disease in children. For example, a healthy 3-month-old infant developed meningitis associated with a rise in titer of reovirus-specific antibodies and the isolation of type 1 reovirus from the cerebrospinal fluid (CSF).²⁴⁶

In another case, type 2 reovirus was isolated from CSF and stool of an 8-week-old girl with meningitis.²¹⁸ This child was subsequently found to have a congenital immunodeficiency with hypogammaglobulinemia. In a third case of reovirus-associated meningitis, type 3 reovirus was isolated from CSF of a 7-week-old child without other known morbidities.⁴⁹⁴ This virus was shown to produce encephalitis in mice.

Reovirus also has been associated with acute necrotizing encephalopathy (ANE), a CNS inflammatory condition that occurs a few days after the development of respiratory symptoms, often in association with influenza.^{230,334} Two cousins, a 6-year-old boy and a 22-month-old girl, were hospitalized in Tours, France with fever and neurologic symptoms following brief illnesses characterized by headache and rhinorrhea in the boy and girl, respectively.³⁷⁰ MRI scans of both children demonstrated characteristic abnormalities of ANE: high signal intensity on T2-weighted images in the thalami bilaterally, brainstem tegmentum, and cerebral white matter in external capsules. Type 2 reovirus was isolated from urine of both children and a throat swab from the girl.³⁷⁰ Culture and PCR tests were negative for other pathogens. Both children also developed reovirus-specific antibodies. Sequence analysis indicated that the reovirus isolates from these patients were identical and that most gene segments closely resembled strains circulating in China. Interestingly, a family member had returned from Indonesia a few days before the onset of symptoms in the children. No illness was reported in the returning traveler.

Myocarditis

Although certain reovirus strains cause myocarditis in newborn mice,^{363,448,451} reovirus is an unusual cause of myocarditis in humans. There is one case report of a possible association of reovirus infection with myocarditis in an adult.⁴⁸⁶ A 28-year-old man developed fever associated with transient paroxysmal atrial fibrillation and premature ventricular contractions in the absence of cardiac enzyme elevation. Stool culture yielded a reovirus isolate of unspecified serotype. Serologic studies and cardiac biopsy were not performed. It is possible that the reovirus strain isolated from stool contributed to the cardiac abnormalities, but this inference remains unproven.

Pneumonia

The fusogenic reoviruses have been associated with respiratory infections in humans. Melaka virus was isolated from a 39-year-old man in Melaka, Malaysia with fever and pneumonia.⁹⁶ Two family members developed similar symptoms 1 week after his illness and had serologic evidence of infection with the same virus. It is thought that Melaka virus was transmitted to the index case by an infected bat. Melaka virus encodes a FAST protein and produces syncytia in mammalian cells. The genome organization of the Melaka virus polycistronic S1 gene segment most closely resembles that of Pulau virus (another bat-borne fusogenic orthoreovirus) and NBV.⁹⁶ A closely related virus, Sikamat virus, was isolated from a 46-year-old man in Sikamat, Malaysia with fever, pharyngitis, and myalgia.⁹⁸ The man and his family had regularly visited an orchard frequented by fruit bats. Two family members had serologic evidence of Sikamat virus infection, but neither became ill. These cases illustrate the propensity of orthoreoviruses to spillover from bats to humans and suggest that targeted surveillance will reveal additional bat-borne zoonotic reovirus infections.

Diagnosis

Reovirus infections can be diagnosed by isolating virus from tissues or body fluids, detecting viral protein or RNA in patient samples, or demonstrating increases in reovirus-specific antibody titer. Reovirus has been isolated from nasal washings, throat swabs, urine, stool, and CSF. Monkey kidney cells have generally been considered optimum for isolating reovirus from clinical specimens, but reovirus infects most cells that are routinely maintained in clinical microbiology laboratories.⁴⁹⁵ In addition to characteristic cytopathic effect, the presence of reovirus proteins can be confirmed using either immunofluorescence or immunocytochemistry to detect reovirus proteins in infected cell cultures.⁴⁹⁵ Immunohistochemical techniques also can be employed for detection of reovirus proteins in tissue specimens.⁴⁹⁵ Determination of viral serotype can be accomplished using plaque-reduction neutralization or hemagglutination-inhibition assays with type-specific antisera. Sequence analysis of the S1 gene segment can be used to confirm the isolate serotype.^{137,494}

A variety of RT-PCR protocols have been established to detect reovirus RNA in blood or tissue samples. Primers specific for the L1,⁴⁹⁹ L3,⁴²⁴ M3,⁴⁷¹ and S4⁵⁵ gene segments have been used for this purpose. Primers specific for these and other gene segments also have been used to detect reovirus in cultured cells. The sensitivity and specificity of these protocols have not been established.

Reovirus-specific antibodies in serum can be detected by enzyme-linked immunosorbent assays^{399,437,482} and immunoblotting.^{370,437} Results can be confirmed by plaque-reduction neutralization or hemagglutination-inhibition assays.

Treatment

There are no established therapeutic modalities for reovirus infections in humans. Studies using cultured cells and experimental animals suggest that inhibition of either viral RNA synthetic capacity or host functions required for viral infectivity may have efficacy. Ribavirin, a broad-spectrum inhibitor of viral RNA synthesis, has antiviral activity against reovirus in cultured cells,^{111,392} but this drug has not been tested in animals. The inosine monophosphate dehydrogenase inhibitor, mycophenolic acid, inhibits the replication of both mammalian and avian reovirus strains in cultured cells by blocking viral transcription.^{219,402} There are no reports of this drug being used to treat reovirus infections *in vivo*.

A variety of pharmacologic inhibitors of host functions required for reovirus internalization and disassembly decrease reovirus yields in cultured cells. For example, chlorpromazine, which impedes clathrin-dependent uptake, chloroquine, which blocks endosomal acidification, and CLIK-148, which inhibits cathepsin L, arrest reovirus infection.^{247,298,306} Of these inhibitors, only CLIK-148 has been tested in animals; this drug diminishes reovirus loads and enhances survival in infected mice.²⁴⁷

Pharmacologic manipulation of host innate immune and apoptotic pathways dampens disease in mice infected with reovirus. Type 1 IFNs diminish reovirus infection in cultured cells^{242,452} and ameliorate reovirus-induced myocarditis³⁶³ and encephalitis in mice.¹⁴⁴ Minocycline delays disease onset and mortality in reovirus encephalitis in association with diminished viral loads and virus-induced apoptosis.³⁹⁷ Caspase inhibitors^{131,398} and a cell-permeating JNK inhibitor³⁵ have similar effects. Such strategies

may have efficacy in the treatment of other viral infections in which apoptosis is a major contributor to tissue pathology.

Passive administration of antiviral antibodies^{497,502,508} or virus-specific immune cells^{450,509} can protect mice infected with otherwise lethal doses of reovirus. Remarkably, both humoral and cell-mediated immune effectors can protect against lethal challenge even when administered after viral inoculation.

REOVIRUS ONCOLYTICS

The capacity of mammalian reoviruses to specifically infect and replicate in transformed cells was first noted in the late 1970s.^{152,212} Subsequent work showed that cells overexpressing native or truncated forms of the epidermal growth factor receptor are more susceptible to reovirus infection.^{477,479} This observation led to the discovery that cells with activated Ras signaling pathways are similarly more susceptible to reovirus infection.¹⁰⁸ In the last 15 years, several viruses have been tested in clinical trials for efficacy in the treatment of cancer. Reovirus strain T3D (Reolysin®, Oncolytics Biotech Inc.) is being tested for antineoplastic efficacy in phase I, II, and III clinical trials in humans (Table 44.5). However, other reovirus strains also appear to infect and kill transformed cells.¹¹

Although transformed cells with activated Ras signaling pathways are more susceptible to reovirus infection,⁴⁷⁶ those in which Ras pathways are not activated are also susceptible.⁴⁶⁴ The underlying mechanism for preferential replication of reovirus in transformed cells is not fully understood. However, a variety of factors enhance the susceptibility of transformed cells to reovirus-induced cell killing. These include a failure of transformed cells to mount a normal IFN response,⁴⁵⁴ enhanced proteolytic disassembly of the virus in the tumor microenvironment,^{10,307} increased receptor availability in tumor tissue,⁵⁰⁴ decreased particle-to-infectivity ratios of virus produced in

transformed cells, and increased virus release associated with caspase-mediated apoptosis.³⁰⁷ How cellular transformation enhances these processes is not known. However, stabilization of the p53 tumor suppressor protein enhances reovirus-induced apoptosis as a consequence of increased activation of NF-κB.³⁷² Increased reovirus-induced apoptosis in transformed cells also is associated with increased virus release and spread.^{307,372}

Reovirus T3D has been evaluated for oncolytic activity against a variety of tumors in animal models and humans (Table 44.5). Early studies of antitumor efficacy showed that human malignant glioma cell lines are susceptible to killing by reovirus.^{108,528} Subsequent work using tumor cell lines and animal models showed that reovirus can infect human bladder cancer,²⁵⁵ breast cancer,³⁶¹ colonic and ovarian tumors,²²² gastric cancers,²⁵² lymphoid tumors,⁹ medulloblastoma,⁵³⁸ melanoma,¹⁶² non-small-cell lung cancer,⁴³⁶ pancreatic cancer,¹⁶³ pediatric sarcomas,²²¹ and prostate cancer.⁴⁹⁰ In clinical trials performed thus far, reovirus is well tolerated in humans when given at doses of up to 3×10^{10} TCID₅₀ intravenously.¹⁹⁴ However, safety in immunodeficient persons has not been reported. Reovirus can systemically target metastatic tumors in animal models^{220,223} and humans⁵⁰⁷ and also is being evaluated for use as an *ex vivo* purgative for autologous stem cell transplantation.^{488,489} Reovirus oncolytic activity is increased when combined with chemotherapy or radiation (reviewed in 210).

PERSPECTIVES AND NEXT STEPS

Since its discovery more than 50 years ago, reovirus has been used to make numerous important contributions to the field of virology. The ability to manipulate the genome of both virus and host makes reovirus a tractable experimental system for studies to precisely define viral and host determinants of pathogenesis. The application of genetics, biochemistry,

TABLE 44.5 Completed Clinical Trials of Reovirus for the Treatment of Human Cancers^a

Cancer indication and phase	Method of delivery and therapeutic combination
Sarcomas metastatic to the lung (phase II)	Intravenous Reolysin ^b monotherapy
Metastatic melanoma (phase II)	Intravenous Reolysin monotherapy
Advanced head and neck cancers (phase II)	Intravenous Reolysin combined with paclitaxel and carboplatin
Advanced malignancies including melanoma and lung and ovarian tumors (phase I/II)	Intravenous Reolysin combined with paclitaxel and carboplatin
Advanced malignancies including bladder, prostate, lung, and upper gastrointestinal tumors (phase I)	Intravenous Reolysin combined with docetaxel
Advanced malignancies including pancreatic, lung, and ovarian tumors (phase I)	Intravenous Reolysin combined with gemcitabine
Various metastatic tumors, including head and neck tumors (phase II)	Intratumoral administration of Reolysin combined with low-dose radiotherapy
Recurrent malignant glioma (phase I/II)	Intratumoral infusion of Reolysin
Various metastatic tumors (phase I)	Intratumoral administration of Reolysin combined with radiotherapy
Various metastatic tumors (phase I)	Intravenous Reolysin monotherapy
Recurrent malignant glioma (phase I)	Intratumoral administration of Reolysin
Cancer confined to the prostate (phase I)	Intratumoral administration of Reolysin
Various progressive subcutaneous tumors (phase I)	Intratumoral administration of Reolysin

TABLE 44.6 Key Unanswered Questions in Studies of Mammalian Reoviruses

1. What host molecules are used as reovirus receptors at sites of primary and secondary replication?
2. How does reovirus sort in the endocytic pathway?
3. How does reovirus penetrate membranes?
4. How are nonpolyadenylated reovirus mRNAs efficiently translated?
5. How do reovirus replication complexes form and function?
6. How are reovirus core particles and virions assembled?
7. How does reovirus disseminate systemically?
8. How does reovirus cause tissue injury?
9. How does reovirus activate and evade host innate and adaptive immune responses?
10. What is the basis and efficacy of reovirus oncolysis?

cell biology, and structural analyses has yielded a wealth of information about mechanisms that govern reovirus tropism, cell entry, replication, and disease. However, important questions remain (Table 44.6). Perhaps most enigmatic is why reovirus infection is so infrequently associated with disease. A crucial corollary question is whether mounting reports of fusogenic orthoreovirus infections of humans in Asia portend the emergence of more virulent reovirus strains in the future. As reovirus shares a number of features with more pathogenic viruses, it is likely that answers to these questions will reveal broadly conserved principles of virus biology and may illuminate new targets for broad-spectrum antiviral therapeutics and vaccines.

Rapidly advancing clinical applications will set future directions for reovirus research. Reovirus infects transformed cells more efficiently than it does nontransformed cells.¹⁵² Based on initial success in using reovirus for tumor killing in animal models,^{108,222} reovirus is currently undergoing evaluation in clinical trials as a virotherapeutic for aggressive and treatment-refractory human cancers.⁴⁷⁵ Reovirus undergoes primary replication in intestinal tissue with few or no symptoms in humans and is now amenable to genetic modification.²⁶¹ Therefore, it also is an excellent candidate for development of multifunctional vaccines to elicit mucosal immunity. Ongoing research to understand mechanisms by which reovirus engages host cells and initiates an infectious cycle will guide strategic retargeting of reovirus to selected host cells and tissues to maximize oncolytic and immunostimulatory potential.

ACKNOWLEDGMENTS

We acknowledge Bernard Fields, Max Nibert, Leslie Schiff, and Ken Tyler for contributions to chapters about reoviruses in previous editions of *Fields Virology*. We thank Karl Boehme, Jim Chappell, Kevin Coombs, Pranav Danthi, Roy Duncan, Geoff Holm, Peter Mertens, Thilo Stehle, and members of our laboratories for essential discussions and critical review of the text. We thank Dirk Reiter and Denise Wetzel for assistance with the figures. Our work has been funded by the National Institutes of Health and the Lamb Center for Pediatric Research.

diseases (a) are one of the most common illnesses in this age group throughout the world; (b) are one of the six leading causes of 10.6 million deaths that occur annually in children younger than 5 years of age; and (c) account for 18% (i.e., greater than 2 million) of the 10.6 million deaths,⁸⁹ with the greatest toll being in developing countries.^{89,788}

Viruses were first discovered to be significant causes of diarrheal illness in the 1970s, with Norwalk virus being the first agent discovered in 1972 by Kapikian et al⁴⁰⁰ from an outbreak of gastroenteritis in a school in Norwalk, Ohio. The Norwalk and related viruses, now known as noroviruses, are members of the genus *Norovirus* of the family *Caliciviridae* (see Chapter 20). Human rotaviruses were discovered in 1973, when particles were visualized by Bishop et al^{59,60} in electron micrographs of thin sections of duodenal mucosa and later virus was identified in feces by electron microscopy (EM).^{58,246,398,505} Both of these fastidious gastroenteritis viruses were discovered without the benefit of tissue culture technology; their identification relied on direct visualization by EM. The 70-nm particles (Fig. 45.1)^{388,398} from children's feces were subsequently designated rotavirus²⁴⁷ and documented to be an important etiologic agent of severe diarrhea of infants and young children during the first 2 years of life^{56,391} in both developed and developing countries (Fig. 45.2); rotaviruses consistently outranked in importance other known etiologic agents of severe diarrhea.³⁹⁰

Although the human rotaviruses were discovered in 1973, several animal viruses were described during the previous 10 years that were later found to be rotaviruses based on exhibiting characteristic rotavirus morphology and sharing a group antigen with human rotaviruses.^{247,393} These animal agents included (a) the epizootic diarrhea of infant mice (EDIM) virus seen by Adams and Kraft,⁴ using thin-section EM in intestinal tissue of mice infected with EDIM virus; (b) a 70-nm simian agent 11 (SA11) that was cultivated in vervet monkey kidney cells from a rectal swab obtained from a healthy vervet monkey⁴⁷⁰; (c) the O (offal) agent isolated in vervet monkey kidney cell culture from the mixed washings of intestines of cattle and sheep⁴⁷¹; and (d) 70-nm virus particles in stools from calves with a diarrheal illness that could be passaged serially in calves and produce disease,⁴⁹⁸ were also cultivated in primary fetal bovine cell cultures, and were named the Nebraska calf diarrhea virus (NCDV).⁴⁹⁹ Thus, rotaviruses were excreted in stools of many species and frequently associated with diarrheal disease.

INTRODUCTION AND HISTORY

Rotaviruses are the single most important cause of severe diarrheal illness in infants and young children in both developed and developing countries worldwide, accounting for 30% to 50% of these illnesses.^{45,562,563–564} Regardless of cause, diarrheal

CLASSIFICATION

Rotaviruses are members of the genus *Rotavirus* within the family *Reoviridae*, and rotaviruses share common morphologic

FIGURE 45.1. Schematic diagram and electron micrograph of rotavirus particles. A: The particle is composed of three concentric protein shells (VP7, VP6, and VP2, shown in different colors) and the spike protein VP4 that spans the VP6 and VP7 layers and extends out from the particle. A transcription complex of VP1 and VP3 is inside the VP2 layer. The viral double-stranded RNA (dsRNA) genome is segmented. **B:** Rotavirus triple-layered particles (TLPs) and a few double-layered particles (DLPs) (arrows) are easily visualized by electron microscopy (**right panel**). Bar, 100 nm.

and biochemical properties (Table 45.1). Early studies using negative-stain EM techniques underestimated the particle diameter, and the subsequent cryo-EM studies, in which no stains are used, established the particle diameter to be 100 nm including the spikes. Salient features are that (a) mature virus particles, including spikes, are about 100 nm (1,000 Å) in diameter and possess a triple-layered icosahedral protein capsid composed of an outer layer, an intermediate layer, and an inner core layer; (b) 60 protein spikes extend from the smooth surface of the outer shell; (c) outer capsid integrity requires calcium; (d) particles contain an RNA-dependent RNA

polymerase and other enzymes capable of producing capped RNA transcripts; (e) the virus genome contains 11 segments of double-stranded RNA (dsRNA); (f) rotaviruses of the same group (see later) are capable of genetic reassortment; (g) virus replication occurs in the cytoplasm of infected cells; (h) virus cultivation *in vitro* is facilitated by treatment with proteolytic enzymes enhancing viral infectivity by cleavage of the outer capsid spike polypeptide; and (i) the viruses exhibit a unique morphogenic pathway (transiently enveloped virus particles are formed by budding into the endoplasmic reticulum [ER]) during morphogenesis. Mature particles are nonenveloped,

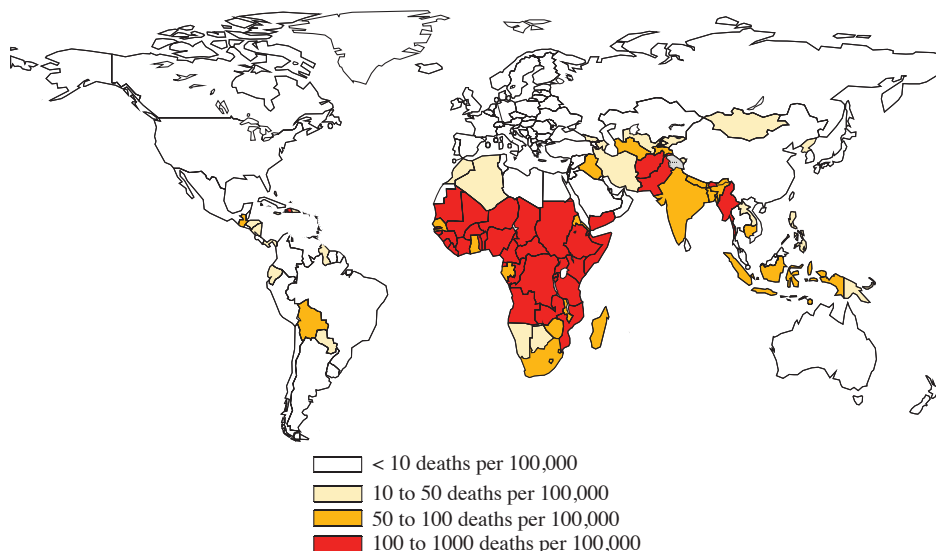

FIGURE 45.2. Rates of rotavirus mortality among children younger than 5 years of age by country. Colors indicate number of deaths per 100,000. (Data for 2008 from Umesh Parashar, Centers for Disease Control and Prevention.)

TABLE 45.1 General Characteristics of Rotaviruses

Structure
100-nm icosahedral particles (including the spikes)
Triple-layered protein capsid
Nonenveloped (resistant to lipid solvents)
Capsid contains all enzymes for mRNA production
Genome
11 segments of dsRNA
Purified RNA segments are not infectious
Each RNA segment codes for at least one protein
RNA segments from different viruses reassort at high frequency during dual infections of cells
Replication
Cultivation facilitated by proteases
Cytoplasmic replication
Inclusion body formation
Unique morphogenesis involves transient enveloped particles
Levels of intracellular calcium important for virus assembly and stability
Virus particles released by cell lysis or by nonclassical vesicular transport in polarized epithelial cells

mRNA, messenger RNA; dsRNA, double-stranded RNA.

and virions are liberated from infected cells by cell lysis or by a nonclassic vesicular transport in polarized epithelial cells.

Rotaviruses are classified serologically by a scheme that allows for the presence of multiple groups (serogroups, based on VP6 reactivity) and of multiple serotypes within each group (based on VP4 and VP7 neutralizing epitopes). Rotaviruses are composed of seven distinct groups (A to G, now designated RVA, RVB, RVC, etc.). RVA, RVB, and RVC strains are found in both humans and animals, whereas rotaviruses of groups D, E, F, and G have been found only in animals to date. Viruses within each group are capable of genetic reassortment, but reassortment does not occur among viruses in different groups, and thus RV groups are considered unique species.⁸⁰⁶ A rotavirus group includes viruses that share cross-reacting antigens detectable by a number of serologic methods, such as immunofluorescence, enzyme-linked immunosorbent assay (ELISA), and immune electron microscopy (IEM). Cross-reactive epitopes on the inner capsid protein (VP6) are those usually detected by diagnostic ELISA, primarily because this protein is highly antigenic and it represents the largest mass of the particle. However, common antigens are found on most (if not all) of the structural proteins and probably on many of the nonstructural proteins as well. This is documented by observing that monospecific antisera and some monoclonal antibodies (mAbs) specific for individual polypeptides cross-react with strains other than those to which they were made.

RVAs cause significant diarrheal disease in infants and in the young of various mammalian and avian species. RVBs have been associated with epidemics of severe diarrhea primarily in adults in Asia.^{355,655,700} RVCs have been sporadically reported in fecal specimens from children with diarrhea and in several family outbreaks.⁵⁵⁷ Rapid diagnostic tests (ELISA), mAbs, and polymerase chain reaction (PCR) assays to detect non-

group A rotaviruses are available mainly in research laboratories, and these facilitate determining the clinical importance of these viruses.^{534,807} Very few non-group A rotavirus strains have been successfully propagated in cell culture. The inability to grow most non-group A viruses has hampered obtaining detailed information on these viruses, although gene-coding assignments and sequence data are available. Unless noted otherwise, this chapter focuses on information about the RVA viruses. Reviews on the non-group A rotaviruses and comparisons between the proteins of the group A and non-group A viruses have been published elsewhere.^{80,374,486,655}

Within RVA, viruses are classified into serotypes defined by reactivity in plaque reduction (or fluorescent foci reduction) neutralization assays using hyperimmune serum prepared in antibody-negative animals. With such assays, 27 VP7 (or G [for glycoprotein]) serotypes have been identified (Table 45.2), and strains of animal and human origin may fall within the same G serotype. Neutralization assays can measure reactivity of antibody against the two outer capsid neutralizing antigens (VP7 and VP4, Tables 45.2 and 45.3). In most cases, however, the predominant reactivity measured when using hyperimmune antisera is against the glycoprotein VP7. This may be because VP7 makes up a greater percentage of the virion outer capsid than VP4 does, or alternatively, with hyperimmunization, VP7 selectively induces highly specific antibodies. The protein specificity of neutralizing antibodies after primary and secondary infection is less well defined. Identical classification of the same virus isolates using mAbs to VP7 unequivocally demonstrates that plaque-reduction neutralization assays with hyperimmune serum *primarily* measure reactivities with VP7.^{54,155,708}

In some cases, a rotavirus strain will not react clearly in reciprocal neutralization assays with hyperimmune antiserum. This is usually because the two viruses being compared possess distinct immunologic forms of VP4 (the second outer capsid protein), which is also a neutralization antigen (Table 45.3). Many mAbs to VP4 possess neutralization activity. Because the genes encoding these two distinct neutralization antigens can segregate (reassort) independently, it is not surprising that some virus isolates possess heterologous neutralization (VP4, VP7) antigens.²⁴⁹ Rotaviruses are classified by a binary system (similar to that used for influenza viruses) in which distinct types of VP4 and VP7 are recognized.^{296,345,634} A lack of readily available typing serum or mAbs to different VP4 types, however, has hampered classification of VP4 (or P [for protease-sensitive protein]) serotypes. Instead, properties of VP4 have been studied primarily by sequence analysis, and current evidence indicates the existence of at least 35 different genotypes of VP4 (Table 45.3). Genotypes of VP4 and VP7 are determined by sequence analysis, whereas serotypes are determined by reactivity of individual strains or selected reassortants with polyclonal or monoclonal antisera.^{216,343} For VP7, a correlation between genotype and serotype has been established. Such a correlation is much less clear for VP4, although a variable region on VP8* that spans amino acid (aa) 71 to 204 can define P type-specific epitopes.²⁸⁹ Serotype designation, thus, reflects the expression of neutralization epitopes on both VP4 and VP7. The serology of the epitopes in proteins that interact in the capsid is complicated but is beginning to be understood with the availability of high-resolution structural data on these outer capsid proteins.

In 2008, a comprehensive nucleotide sequence-based, complete genome classification system was developed for

TABLE 45.4 Nucleotide Percentage Identity Cut-off Values Defining Genotypes for 11 Rotavirus Gene Segments

Gene product	Percentage identity	Genotypes	Name of genotypes
VP7	80	27G	Glycosylated
VP4	80	35P	Protease sensitive
VP6	85	16I	Inner capsid
VP1	83	9R	RNA-dependent RNA polymerase
VP2	84	9C	Core protein
VP3	81	8M	Methyltransferase
NSP1	79	16A	Interferon Antagonist
NSP2	85	9N	NTase
NSP3	85	12T	Translation enhancer
NSP4	85	14E	Enterotoxin
NSP5	91	11H	PHosphoprotein

Modified from Matthijnsens J, Ciarlet M, Rahmanet M, et al. Recommendations for the classification of group A rotaviruses using all 11 genomic RNA segments. *Arch Virol* 2008;153:1621–1629.

RVAs.⁴⁸³ This system assigns a specific genotype to each of the 11 RV genome segments according to established nucleotide percent cutoff values. The *VP7-VP4-VP6-VP1-VP2-VP3-NSP1-NSP2-NSP3-NSP4-NSP5/6* genes of RV strains are described using the abbreviations Gx-P[x]-Ix-Rx-Cx-Mx-Ax-Nx-Tx-Ex-Hx (x = Arabic numbers starting from 1), respectively (Table 45.4). A Rotavirus Classification Working Group that includes researchers worldwide maintains and evaluates this system. Recent updates are published and new guidelines recommend uniform nomenclature for individual strains to be RV group/species of origin/country of identification/common name/year of identification/G and P type.⁴⁸² The prototype simian agent 11 is designated RVA/Simian-tc/ZAF/SA11-H96/1958/G3P5B[2] and the full descriptor of genes is

indicated by G3-P[2]-I2-R2-C5-M5-A5-N5-T5-E2-H5 using this new system.

VIRION STRUCTURE

The morphologic appearance of rotavirus particles is distinctive, and three types of particles can be observed by EM (Fig. 45.3). The complete particles resemble a wheel with short spokes and a well-defined, smooth outer rim. The name *rotavirus* (from the Latin *rota*, meaning “wheel”) was coined based on this morphology.²⁴⁷ The complete infectious particles (virions) are also called *triple-layered particles* (TLPs). These particles are ~100 nm in diameter, which is relatively large for a nonenveloped, icosahedral virus. Double-layered particles (DLPs) lacking the outer shell are described as *rough particles* because their periphery shows projecting trimeric subunits of the inner capsid. Single-layered particles (SLPs or cores) are seen infrequently; they usually lack genomic RNA and are aggregated.

The structures of triple- and double-layered rotavirus particles are solved to near-atomic resolution based on x-ray crystallography and particle reconstructions of cryo-electron microscopy (cryo-EM) images, and these provide a detailed description of particles^{121,434,435,440,488,605,675,679,803,828} (Fig. 45.4). Particles possess icosahedral symmetry with a T = 13I (levo) icosahedral surface lattice for the two outer layers, while the innermost layer exhibits a unique T = 1 icosahedral organization. Distinguishing features of the TLP structure include 132 large aqueous channels and 60 spikes.

The channels span the two outer layers and link the outer surface with the inner core. Three types of channels are distinguishable based on their position and size. Twelve type I channels are located at the icosahedral fivefold axes, 60 type II channels are at each of the pentavalent positions surrounding the fivefold axes, and a second set of 60 type III channels are at the six-coordinated positions surrounding the icosahedral threefold axes. Type III channels are about 140 Å in depth and about 55 Å wide at the outer surface of the virus. On entering the particle, these channels constrict before widening to their

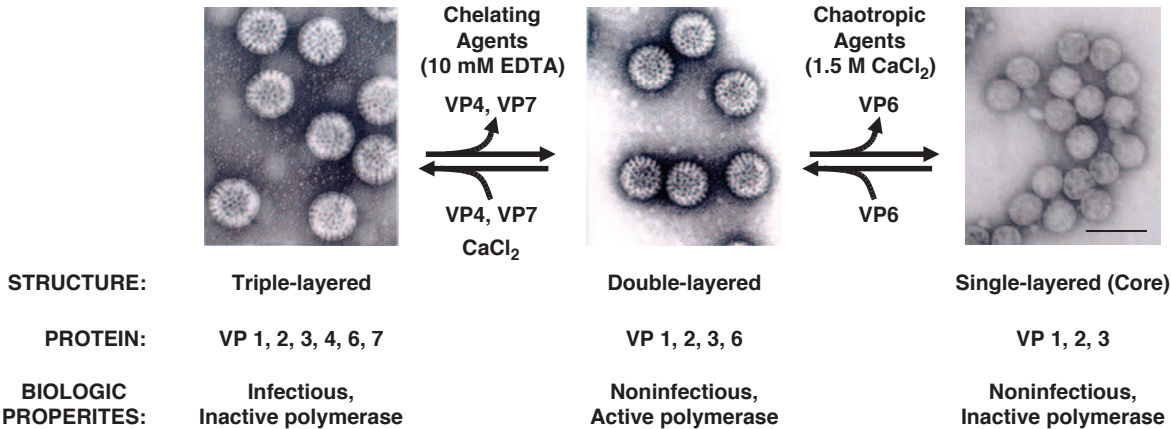

FIGURE 45.3. Structural and biological properties of rotavirus particles. Electron micrographs show typical triple-layered particles (TLPs), double-layered particles (DLPs), and single-layered particles (SLPs) (core) after staining with 1% ammonium molybdate. TLPs, DLPs, and core particles can be produced by sequential capsid protein removal (top arrows) or addition (bottom arrows), as shown. The proteins and biological properties of the particles are detailed in the text. Bar, 100 nm.

FIGURE 45.4. Rotavirus structures and locations of protein components. A cutaway view of a 9.5-angstrom cryo-electron microscopy (cryo-EM) reconstruction of the mature triple-layered rotavirus particle (TLP) shows surface and internal structural features. The TLP is colored with the VP4 spikes (60 trimers) in red, the VP7 (780 trimers) surface glycoprotein in yellow, the internal (middle) VP6 (780 trimers) layer in blue, and the core VP2 (120 dimers) layer in green. Atomic structures of the individual proteins also are shown along with their locations in the virion. Structures made from Protein Data Bank (PDB) IDs: 2R7R (VP1), 3KZ4 (VP2), 3IYU (VP4), VP6 (3KZ4), 3FMG (VP7). The two calcium (Ca^{2+}) molecules coordinated between each of the VP7 monomers are shown in black.

maximal width, which is close to the surface of the inner shell. Similar features and dimensions are seen in the other two types of channels, except that type I channels have a narrower (~ 40 Å) opening at the outer surface of the virus. The type I channels are conduits for the export of messenger RNA (mRNA) that first interacts with the enzyme complexes composed of VP1, the RNA-dependent RNA polymerase, and VP3, the methyltransferase and guanylyltransferase, that are present at the inner surface of the fivefold axes of the SLP^{432,435,604} (see Fig. 45.4). Atomic structures of the rotavirus polymerase, alone and in complex with RNA, show VP1 is a compact, globular protein of ~ 70 Å in diameter that has three domains: an N-terminal domain, a polymerase domain, and a C-terminal domain.⁴⁶⁰ The polymerase domain exhibits the right-handed architecture (fingers-palm-thumb) typical of polymerases in general as well as canonical motifs (A to F) involved in various aspects of phosphodiester bond formation^{461,546} (Fig. 45.4). The N-terminal and C-terminal domains envelop the polymerase domain, creating a cage-like enzyme with a hollow catalytic center. Four tunnels lead into the center, serving as conduits for the entry and exit of free nucleotides (nucleoside triphosphates [NTPs]), template RNAs, and RNA products. This solved structure represents a catalytically inactive form of the polymerase captured prior to the initiation of dsRNA synthesis. Models of how

this enzyme functions in coordinated genome replication and packaging are discussed later.

The single-layered particle exhibits a unique $T = 1$ symmetry and is composed of 120 molecules of VP2 arranged as 60 dimers that surround the genomic dsRNA that is highly ordered^{434,488,604} (Fig. 45.4). X-ray and cryo-EM structures of DLPs show that VP2 has two structural isoforms that interact extensively. One of the subunits in the asymmetric unit (VP2A) packs around the icosahedral fivefold axis forming a star-shaped complex with a small pore in the middle lined by conserved basic residues. The other subunit (VP2B) fills in space between the VP2A subunits forming a decameric cap structure at the fivefold axis. Twelve of these decameric complexes make up the VP2 layer that is 25 to 30 Å thick. Many segmented dsRNA viruses contain 120 molecules of a core protein (VP2 for rotavirus, VP3 for bluetongue virus, lambda 1 for reoviruses, the single capsid protein for cypovirus) that surrounds an ordered genome.^{307,337,825} Although the inner shell protein shares similar features among these dsRNA viruses, rotaviruses and orbiviruses are distinguished by housing their enzymatic functions entirely *within* the inner shell, leading them to be called *nonturreted viruses*, and nascent mRNA transcripts are released through channels penetrating the two capsid layers at the icosahedral vertices.^{337,433,434,536} This

capsid architecture contrasts with the structure of the *turreted viruses*, reoviruses,^{624,829} aquareovirus,⁸²⁷ and cypovirus,^{434,536,815} where the polymerase enzyme is housed within the core, but the capping enzymes are incorporated as pentameric turret-like projections that extend through the inner capsid layer at each icosahedral vertex.³³⁷

The VP2 layer is surrounded by 260 trimers of VP6 that form a $T = 13$ icosahedral lattice (Fig. 45.4). These trimers are located right below the VP7 trimers in the outer layer so that the channels are in register. The double-layered particle is about 705 Å in diameter, and the structure of the VP6 subunit has two domains with an overall structure similar to the VP7 of bluetongue virus^{307,478} (Fig. 45.4) and to the $\mu 1$ protein of orthoreovirus.⁴⁴² The distal domain of rotavirus VP6 has an eight-stranded jelly-roll β -barrel fold that makes contacts with VP7 and VP4, whereas the proximal domain with a cluster of eight α -helices and a conformationally flexible loop structure in VP6 is involved in establishing optimal contacts with the underlying VP2 subunits.^{488,828} Interactions of VP6 with the VP7 layer at the top and the VP2 layer at the bottom are important in stabilizing the entire rotavirus capsid and integrating the two essential functions of particles: cell entry and endogenous transcription. Structural integrity of the DLP is an essential requirement for endogenous transcription that takes place within the confines of the DLP with capped transcripts exiting through the aqueous type I channels at the fivefold axes.⁴³⁴

Sixty trimeric spikes extend from the smooth surface of the outer shell (Fig. 45.4). These protein spikes are situated at an edge of the type II channels surrounding the fivefold icosahedral axes. The spikes are composed of the protein VP4, as initially shown by seeing that two Fab subunits of mAb to VP4 bind on the sides near the tips of the spikes.⁶⁰⁶ Subsequent cryo-EM studies,^{158,192,587,679} including the most recent study at near-atomic resolution,⁶⁷⁵ confirmed that VP4 is the spike protein and showed that the spike is multidomained with a unique trimeric organization that projects about 120 Å from the surface of the virus with a total radial length of 200 Å. Spikes with well-defined structural features, two distal globular domains, a central body with an approximate twofold symmetry, and a globular domain called the foot domain are only visible in rotavirus particles grown in the presence of trypsin that enhances virus yield.^{158,679,802} Proteolysis cleaves VP4 (88K) into VP8* (28 kD, aa 1 to 247) and VP5* (60 kD, aa 248 to 776), and the cleavage products remain noncovalently associated in the virion (Fig. 45.4 and Table 45.5).

Recent crystallographic structures of VP8* and portions of VP5* as well as cryo-EM analyses at about 4.3 Å resolution indicate that the overall conformation of each VP4 subunit is that of a high loop, with the N-terminal helical segment of VP8* anchored against the C-terminal domain of VP5* in the foot domain of the same polypeptide chain.^{192,194,675} Different conformations including dimers, trimers, and asymmetric domains make up the unique trimeric configuration of the cleaved VP4 spike. Two β -barrel domains of VP5*, at the central body of the spike, adopt a dimeric appearance above the capsid surface, while another VP5* β -barrel of the third VP4 molecule is positioned closer to the capsid surface interacting with the VP7 capsid layer; the globular domains of each of the VP5* polypeptides form a trimeric base anchored inside the type II channels between the VP7 and VP6 capsid layers.^{440,587,675,802} Two VP8* molecules are present at the top of two upright VP5* molecules

and the third VP8* is disordered or may be removed by trypsin cleavage.⁶⁷⁵ Thus, VP4 subunits undergo extensive rearrangements that resemble conformational transitions of membrane fusion proteins of enveloped viruses during entry into cells.¹⁹²

The spike is held in place by interactions with both VP6 and VP7. The spike extends inward about 80 Å where it inserts into the lattice of VP6 trimers at the type II channels that surround the icosahedral fivefold axes. This interaction may template trimerization of cytosolic VP4.⁶⁷⁵ The VP7 shell partly covers the base of the VP4 spike and appears to lock VP4 onto the virion within the type II channel.

The outer 35-Å-thick capsid layer of rotavirus is formed by 260 trimers of the glycoprotein VP7 (37 kD) (Fig. 45.4). VP7 is a calcium-binding protein^{262,648} and consists of two domains: domain I with a disulphide bridge exhibits a Ross-mann fold and domain II with three disulfide bridges exhibits a jelly-roll β -sandwich fold. Two Ca^{2+} ions are bound at each subunit interface in the trimer.¹⁷ Three VP7 subunits interact with each other to form a plate-like trimer that sits on top of the VP6 trimers and the N-terminal arms of three VP7 subunits grip the underlying VP6 trimers and intrude into the VP4 foot cavity. These interactions imply that the VP4 spikes must first be attached to the DLPs prior to the addition of VP7 during virus assembly, and addition of VP7 results in a shift in the underlying VP6 trimers.⁶⁷⁵ This order of outer capsid assembly is supported by *in vitro* reconstitution studies where sequential addition of recombinant VP4 followed by VP7 onto DLPs can produce infectious virus.⁷³¹

It remains to be determined whether the helical heptad repeat or the putative fusion domain in the rotavirus spike protein is important only for virus entry or also during viral morphogenesis in cells, a unique process that involves a budding of particles through the membrane of the ER (see later).

GENOME STRUCTURE AND ORGANIZATION

The viral genome of 11 segments of dsRNA is contained within the virus core capsid. Deproteinized rotavirus genomic dsRNA is not infectious, reflecting that virus particles contain their own RNA-dependent RNA polymerase to transcribe the individual RNA segments into active mRNA. Hydrodynamic studies of the flexibility or “stiffness” of isolated rotavirus RNA segments in solution indicate that packaging of these RNA segments into the rotavirus capsid requires intimate protein–RNA interactions.³⁸⁷ The proteins directly responsible for segment packaging remain unknown; the structural proteins present in core particles (VP1, VP2, and VP3) are obvious candidates, but nonstructural proteins may play a role (see later). The genome RNA is highly ordered within the particle, with about 25% of the genome making up a dodecahedral structure, and VP2 interacts with the RNA. Several points of contact between the inwardly protruding portion of VP2 as well as VP1 and VP3 interact with the RNA surrounding each fivefold axis^{430,604} (Fig. 45.4), and VP2 interactions with the VP1 polymerase are required for replicase activity.^{492,573,824}

The nucleotide sequence of all 11 rotavirus RNA segments for many rotavirus strains are known, and this forms the basis for the new classification system discussed earlier.⁴⁸³ The prototype simian SA11 strain was the first genome completely sequenced. The sequences from different rotavirus strains show

TABLE 45.5 Rotavirus Proteins

Genome segment	Protein product ^a	Nascent polypeptide (Mol. Wt. × 1000) ^b	Mature protein modified	Location in virus particles	Number of molecules per virion ^c	Ts mutant group (mutation) ^d	Function ^e
1	VP1	125	—	Core	12	C (L138P)	RNA-dependent RNA polymerase, ssRNA binding, complex with VP3
2	VP2	102.4	—	Core	120	F (A387D)	RNA binding, required for replicase activity of VP1
3	VP3	98.1	—	Core	12	B (G527D)	Guanylyltransferase, methyltransferase, ssRNA binding, complex with VP1
4	VP4	86.8	Cleaved VP5* (529) VP8* (247) ^f	Outer capsid	120	A (A401T)	P-type neutralization antigen, viral attachment, homotrimer, protease-enhanced infectivity, virulence, putative fusion region
5	NSP1 (NS53)	58.7	—	Nonstructural	780	D (L140V)	Interferon antagonist, putative viral E3 ligase, RNA binding
6	VP6	44.8	—	Inner capsid		G (T10S, D13H)	Subgroup antigen, trimer, subgroup antigen, protection (intracellular neutralization ?); required for transcription
7	NSP3 (NS34)	34.6	—	Nonstructural		NA	Acidic dimer, binds 3' end of viral mRNAs, cellular eIF4G, Hsp90, surrogate of PABP, inhibits host translation
8	NSP2 (NS35)	36.7	—	Nonstructural	780	E (A152V)	Basic, octamer, RNA binding, NTPase, NDP kinase, RTPase, helix-destabilizing activities, forms viroplasms with VP1 and NSP5
9	VP7	37.4	Cleaved signal peptide glycosylation	Outer capsid		K (T280I)	G-type neutralization antigen, glycoprotein calcium-dependent trimer,
10	NSP4 (NS20)	20.3	NS29–NS28 uncleaved signal peptide high mannose glycosylation and trimming	Nonstructural		NA	RER transmembrane glycoprotein, viroporin, intracellular receptor for DLPs, role in morphogenesis of TLPs, interacts with viroplasms and autophagy pathway, modulates intracellular calcium and RNA replication, enterotoxin secreted from cells, virulence
11	NSP5 (NS26)	21.7	28K, O-glycosylated, phosphorylated (different forms)	Nonstructural		J (A182G)	Basic, phosphoprotein, RNA binding, protein kinase, forms viroplasms with NSP2, interacts with VP2 and NSP6
	NSP6	12	Product of second ORF	Nonstructural			Interacts with NSP5, present in viroplasms and most virus strains, RNA binding

ssRNA, single stranded RNA; mRNA, messenger RNA; PABP, poly(A)-binding protein; NTPase, nucleoside triphosphatase; NDP, nucleoside diphosphate; RTPase, RNA triphosphatase; RER, rough endoplasmic reticulum; DLP, double-layered particle; TLP, triple-layered particle.

^aThe virion polypeptides are designated as proposed by Mason et al.⁴⁷⁶ and modified by Liu et al.⁴⁴⁸ and Mattion et al.⁴⁸⁶ VP3 is the protein product of gene segment 3, and VP4 is the protein product of gene segment 4. Early studies failed to unequivocally identify a protein product from genome segment 3; hence, the protein product of genome segment 4 was called VP3 in early publications. When the protein product of genome segment 3 was confirmed to be a structural protein located in the inner core, the genome 3 product was designated VP3 and the genome 4 product was renamed VP4.⁴⁷⁶ In 1994, the nonstructural proteins were renamed NSP1 to NSP5 to facilitate comparisons among these proteins of different virus strains,⁴⁸⁶ and this nomenclature is now accepted. The parentheses in this table show the names of the nonstructural proteins as designated previously (NS followed by a number indicating their apparent molecular weight in thousands determined by electrophoresis in polyacrylamide gels containing sodium dodecyl sulfate). NSP6 has been characterized since 1994.^{287,729}

^bMolecular weights are for simian agent 11 (SA11) proteins and are calculated from the deduced amino acid sequences from the nucleotide sequence and from the longest potential open reading frame. The gene-protein assignment of segments 7 to 9 is for the SA11 strain.

^cCalculated from structural studies of purified virions.^{607,608,803}

^dNA, no mutant assignment. Two groups of temperature-sensitive mutants (tsH and tsI) are not yet mapped to a genome segment. Data compiled from the following sources.^{161,285,472,619}

^eSee text for references.

^fThere are three trypsin cleavage sites in SA11 VP4 at amino acids 231, 241, and 247. The indicated mature products are those based on use of only the preferred second cleavage site.^{451,452}

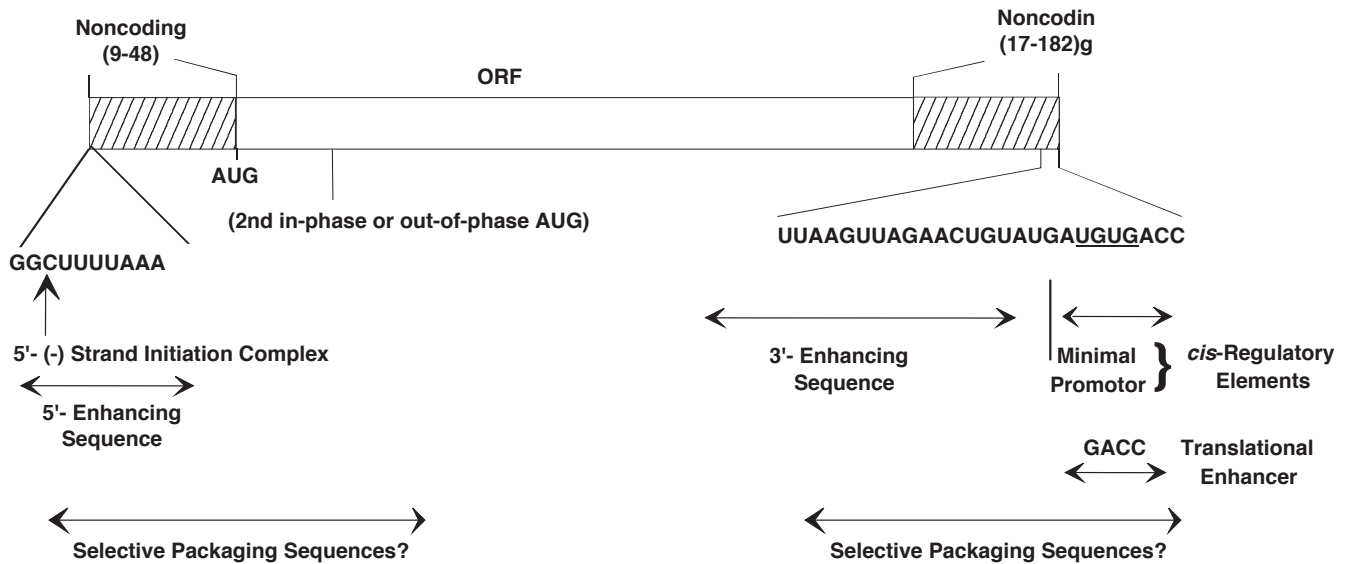

FIGURE 45.5. Major features of rotavirus gene structure. Schematic shows the overall structure of rotavirus genes derived from published sequences of genes 1 through 11. All 11 rotavirus genes lack a polyadenylation signal, are A + U rich, and contain conserved consensus sequences at their 5' and 3' ends. Variations in the conserved ends are also shown. The prototype simian agent 11 (SA11) genome segments range in size from 667 (segment 11) to 3302 (segment 1) with a total of 18,556 base pairs. The bottom arrows show *cis*-regulatory elements of rotavirus messenger RNA (mRNA) required for replication of transcripts assayed in a cell-free replication system.^{404,576,730,786} The study of viruses with variations in the sequence at the 3' termini indicates the minimal promoter is URN_{0.5}CC. The 5' and 3' noncoding regions at the termini of the mRNA are predicted to interact and stably base-pair to form a panhandle structure possibly stabilized by the viral polymerase,^{359,576,730} and interactions between the 3' terminus with the nonstructural protein NSP3 may promote translation of viral mRNA.⁷⁴⁸ The penultimate 5'-GACC-3' is a translation enhancer.¹²⁶

general features (Fig. 45.5) of the structure of each genome segment. Each positive-sense RNA segment starts with a 5'-guanine followed by a set of conserved sequences that are part of the 5' noncoding sequences. An open reading frame (ORF) coding for the protein product and ending with the stop codon follows, and then another set of noncoding sequences is found containing a subset of conserved terminal 3' sequences and ending with two 3' terminal cytidines. Almost all mRNAs end with the consensus sequence 5'-UGUGACC-3', and these sequences contain important signals for gene expression and genome replication. The last four nucleotides of the mRNAs function as translation enhancers.¹²⁶ The lengths of the 3' and 5' noncoding sequences vary for different genes, but the noncoding sequences of homologous strains are highly conserved. No polyadenylation signal is found at the 3' end of the genes. All of the sequenced genes possess at least one long ORF after the first initiation codon. This is usually a strong initiation codon based on Kozak's rules.⁴²⁵ Although some of the genes possess additional in-phase (genes 7, 9, and 10) or out-of-phase (gene 11) ORFs, current evidence indicates that all the genes are monocistronic, except gene 11.⁴⁸⁷

The rotavirus gene sequences are A+U rich (58% to 67%), and this bias against CGN and NCC codons is shared with many eukaryotic and viral genes. The dsRNA segments are base-paired end to end, and the positive-sense strand contains a 5' cap sequence m⁷GpppG^(m)GC.^{359,580} Similar features of the RNA termini (capped structures and 5' and 3' conserved sequences) are found in the genomes of other segmented viruses (e.g., reovirus, cytoplasmic polyhedrosis virus, orbivirus) in the family *Reoviridae* and in other virus families with segmented RNA genomes

(*Orthomyxoviridae*, *Arenaviridae*, and *Bunyaviridae*). One of the most intriguing aspects of the replication cycle of rotaviruses and all segmented dsRNA viruses relates to mechanism(s) of how these viruses coordinately replicate and package the 11 viral mRNAs. The 11 mRNAs must share common *cis*-acting signals because they are all replicated by the same polymerase, and the UGUG sequence of the consensus sequence is recognized in a base-specific manner by the polymerase.^{460,461} In addition, each mRNA must also contain a signal that is unique to it alone, because the 11 mRNAs must be distinguished from one another during packaging. Generally, the conserved terminal sequences in genome segments contain *cis*-acting signals that are important for transcription, RNA translation, RNA transport, replication, assembly, or encapsidation of the viral genome segments. Some of the *cis*-acting signals for rotavirus RNA replication and translation have been identified (Fig. 45.5), but assembly or encapsidation signals remain unknown.⁵⁷⁴ The highly conserved noncoding regions of the RNA may contain the gene-specific packaging signals. Sequence comparisons between RV strains have contributed to identifying conserved sequences and/or secondary structures in the RV genome.⁴³⁹ Conserved secondary structures in the positive-sense RNAs, including long-range interactions at the 5' and 3' terminal regions present in all segments, may facilitate RNA circularization, although such structures remain to be detected in cells.⁴³⁹ Computer modeling and RNase mapping experiments predict that viral (+)RNAs fold into panhandles through 5' and 3' base pairing and the 3' consensus sequence extends from the panhandle as a single-stranded tail.^{116,439,730} Interactions of this extended RNA with different rotavirus and cellular proteins are thought to regulate whether

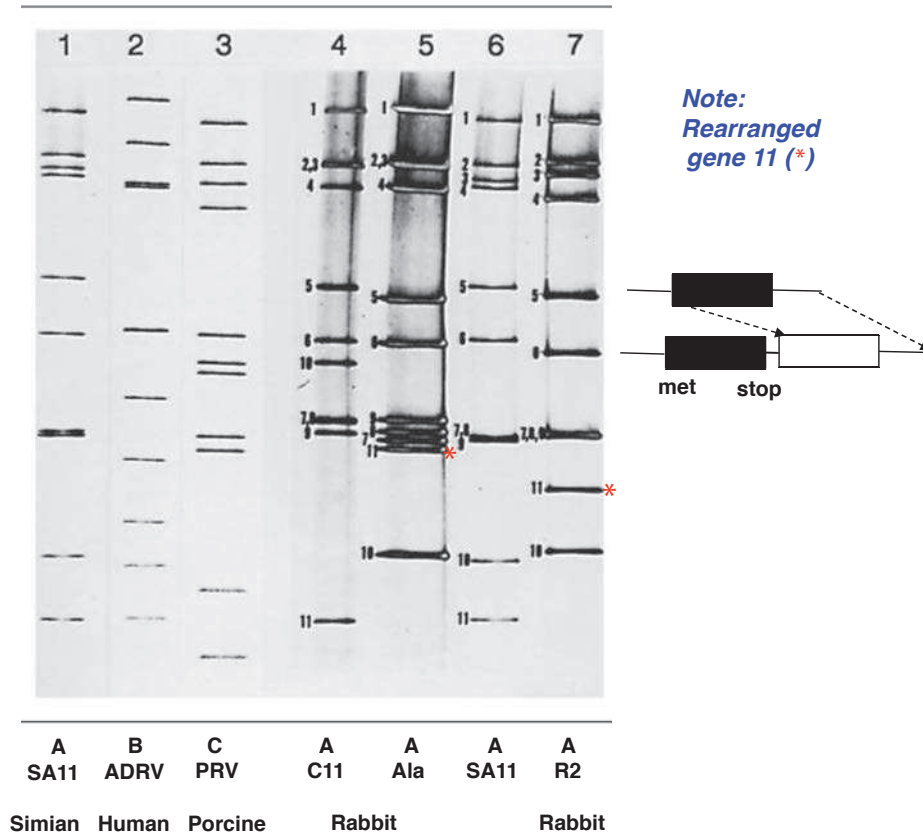

FIGURE 45.6. Electropherogram of rotavirus RNA segments. The RNA segments were separated by electrophoresis in a 10% polyacrylamide gel and visualized by staining with silver nitrate. The RNA patterns of a group A rotavirus (simian agent 11 [SA11], lane 1), a group B rotavirus (adult diarrhea rotavirus isolate from China, lane 2), and a group C rotavirus (lane 3) are shown. The rearranged RNA patterns of three group A rabbit rotavirus strains (C11, lane 4; Ala, lane 5; and R2, lane 7) and their cognate segments compared with those of SA11 (lane 6) are also shown. The cognate genes were identified by hybridization with complementary DNAs (cDNAs) for each SA11 RNA segment. Red asterisks show rearranged gene 11s in the electropherotypes of Ala and R2 viruses. Schematic on right illustrates features of a rearranged gene 11 that has a duplicated open reading frame but would encode a normal protein because it lacks an initiation site in the duplicated ORF. (From Tanaka et al.⁷⁰⁶ et al. Molecular characterization of three rabbit rotavirus strains. *Arch Virol* 1988;98: 253–265.)

the (+)RNA functions in translation, genome replication, or assortment and packaging.⁴⁹¹

Rotaviruses are the only known agents of mammals or birds that contain 11 segments of dsRNA. In most cases, the electrophoretic pattern of the genome of the group A viruses is composed of four high-molecular-weight dsRNA segments (numbered 1 to 4), two middle-sized segments (5 and 6), a distinctive triplet of segments (7 to 9), and two smaller segments (10 and 11). When this basic pattern is not seen, the rotavirus being analyzed may be a group A avian virus, a non-group A virus, a group A virus that contains rearrangements within individual genome segments (Fig. 45.6), or a new unique group A virus. Analysis of genomic electropherotypes is a relatively easy, rapid, and popular technique for virus detection and for molecular epidemiology studies to monitor virus outbreaks and transmission. However, because distinct RNA patterns can arise by different mechanisms (reassortment, mutation, rearrangements) and RNA segments of different sequences may co-migrate, these profiles are not useful as a definitive criterion for classification of a virus strain.^{109,220} (See also Molecular Epidemiology, later). Nucleic acid hybridization combined with northern blot was initially used to classify viruses based on the relatedness of genome segments²²⁵ (e.g., to classify genetically related viruses into different genogroups)⁵³¹ and to identify the origin of specific RNA segments in virus reassortants. This method characterized viruses involved in cross-species transmission^{529,530} but is now being replaced by complete genome sequencing, which has clearly identified zoonotic transmission of many rotavirus genes and reassortment.⁴⁷³

In viruses with genome rearrangements, typical RNA segments are missing or are decreased in concentration in an elec-

trophoretic profile and are replaced by additional, more slowly (or rarely more rapidly) migrating bands of dsRNA (Fig. 45.6, lanes 5 and 7). The slowly migrating bands represent concatemeric forms of dsRNA-containing sequences specific for the missing RNA segments, which has been reviewed elsewhere.¹⁸⁴ The more rapidly migrating bands appear to represent deletions. Viruses with genome rearrangements of this type have been isolated most frequently during infection from immunodeficient, chronically infected children, asymptotically infected immunocompetent children, and animals (calves, pigs, or rabbits). Viruses with rearranged genomes have also been obtained *in vitro* after serial high multiplicity of infection passage of tissue culture-adapted rotaviruses. Virus isolates with rearrangements in segments 5, 6, 8, 10, and 11 have been characterized, with the greatest number having rearrangements detected in segments 5 and 11. Viruses with a rearranged segment 11 may have some selective advantage (better growth *in vitro* or stability), so they are detected more easily, rather than occurring more frequently.

Viruses that contain rearranged genome segments are generally not defective, and the rearranged segments can reassort and replace normal RNA segments structurally and functionally. These viruses do not have a growth advantage, but they exhibit a selective advantage for being incorporated in viral progeny, indicating a preferential packaging of rearranged segments into progeny.⁷³⁷ Biophysical characterization of such particles has shown that up to 1,800 additional base pairs can be packaged in particles without causing detectable changes in particle diameter or apparent sedimentation values. The density of particles containing rearranged genomes may be increased, however, and the increase in density is directly proportional to

the number of additionally packaged base pairs.⁴⁹³ Thus, rotaviruses have considerable capacity to package additional genomic RNA, although the upper limit is unknown. Whereas a total of 11 RNA segments are invariably packaged, much less constraint appears to exist on the length of individual RNA segments assembled into the maturing virus particle. Because the amount of viral RNA present in virions can vary by a significant amount (~1,800 nucleotides), a headfull mechanism for RNA packaging, as seen for the dsRNA phage phi6,⁵¹⁰ may not operate for rotaviruses.

In most cases, the profiles of virus-encoded proteins in cells infected with rotaviruses with rearranged genomes are similar to those seen in cells infected with standard rotavirus strains, indicating that the rearrangement of the sequences in a segment leaves the normal reading frames and their expression unaltered. Sequence analyses of rearranged genome segments confirm this and reveal mechanisms by which the rearrangements arise. In most cases, the rearrangements result from a head-to-tail duplication that occurs immediately downstream from the normal ORF and, hence, the rearranged segment retains the capacity to express its normal protein product. In some cases, gene rearrangements result in truncated proteins. In one case, a gene rearrangement in genome segment 5 introduced a point mutation in the ORF and produced a truncated NSP1 lacking the C-terminal half of the protein.³⁵² This rearranged virus is nondefective *in vitro*, indicating the C-terminal

half of NSP1 is nonessential for rotavirus replication, at least in cell culture.³⁵⁰ Another mutant lacking the cysteine-rich zinc finger motif in the genome segment 5 protein, NSP1, is also viable in cell culture.⁷⁰⁷ Rearrangements have also been identified that affect the ORF for NSP3, and analysis of these viruses suggests a mechanism for gene rearrangements in which secondary structures facilitate and direct the transfer of the RNA polymerase from the 5' to the neighboring 3' end of the template during the replication step.²⁶⁶ Genome rearrangements (concatemerization and deletion) are a third mechanism of evolution (in addition to reassortment and mutation) of rotaviruses. The discovery that rearranged segments are preferentially segregated into progeny virions is helpful to identify sequences critical for replication and RNA packaging.¹⁸⁴ While the exact sequences required for packaging remain to be identified, rearranged genomes that are selectively packaged have parts of the 5' ends duplicated, suggesting packaging signals including coding sequences are located in the 5' region of the RNAs.⁷³⁷

CODING ASSIGNMENTS

The coding assignments and many properties of the proteins encoded in each of the 11 genome segments are now well established (Fig. 45.7 and Table 45.5), although new protein functions continue to be identified. Initially protein assignments

FIGURE 45.7. Genome structure of rotavirus simian agent 11 (SA11) virus. RNA segments (in nucleotides) shown in the positive sense and their encoded proteins (in amino acids). The lines at the 5' and 3' termini represent the noncoding regions. A few key functions of the proteins are listed with the letter bolded that is used in a new classification system based on the entire genome. See the text and Tables 45.4 and 45.5 for information on the classification system and more details on gene-coding assignments and locations of known temperature-sensitive mutations.

were determined by *in vitro* translation using mRNA or denatured dsRNA and by analyses of reassortant viruses. Complete coding assignments were known first for SA11, the type species of the *Rotavirus* genus. Comparative studies of other rotavirus strains have shown that the absolute order of migration in gels of cognate genes may differ among virus strains. Identification of cognate genes, therefore, is now routinely achieved from sequence information obtained directly from dsRNA or single-stranded RNA (ssRNA) following reverse transcription-polymerase chain reaction (RT-PCR) amplification followed by analysis of sequence homology with accumulating nucleic acid sequence databases.

The rotavirus genome segments code for structural proteins found in virus particles and nonstructural proteins found in infected cells but not present in mature particles (Table 45.5 and Fig. 45.7). Six of the genome segments code for structural proteins found in virus particles. Another six proteins are nonstructural, with a few tissue culture adapted virus strains lacking NSP6. Early studies often presented conflicting conclusions concerning the numbers and locations of the rotavirus proteins. Many of these conflicts were resolved, as reviewed elsewhere,⁴⁸⁶ when it was recognized that posttranslational modifications (glycosylation, trimming of carbohydrate residues, and proteolytic cleavages) occur after polypeptide synthesis. In addition, strain variations (e.g., the presence of more than one glycosylation site on VP7 in some bovine, equine, porcine, and human rotavirus strains) provide explanations for other differences in polypeptide patterns.

The nomenclature of the viral proteins (as originally proposed for SA11 proteins) designates structural proteins as viral protein (VP) followed by a number, with VP1 being the highest-molecular-weight protein, and proteins generated by cleavage of a larger precursor being indicated by an asterisk (VP4 is cleaved to produce VP5* and VP8*^{212,221}). Initial studies referred to the nonstructural proteins as NS followed by a number indicating the protein's molecular weight. This nomenclature has been replaced by NSP1 to NSP6 to facilitate comparisons among cognate nonstructural proteins of different molecular weights⁴⁸⁶ (Table 45.5). In fact, much of the literature before 1988 refers to the genome segment 4 product as "VP3"; before 1994, NS53 and NS35 were the designations used for what is now referred to as NSP1 and NSP2, and so forth (Table 45.5). The new nomenclature is used throughout this chapter.

STAGES OF REPLICATION

Overview of the Replication Cycle

Figure 45.8 shows a schematic of the rotavirus replication cycle. Most details of this cycle have been obtained from studies of rotaviruses infecting monkey kidney cell monolayers or polarized intestinal epithelial cells. Other information has come from assays to probe specific steps in the replication cycle based on the expression and interaction of individual wild-type or mutated proteins and RNA in *in vitro* systems, and conclusions from these studies are generally confirmed in the context of virus replication systems using confocal microscopy and small interfering RNA (siRNA). One limitation to some current conclusions on protein function is that an efficient reverse genetics system to test results by incorporating any desired

mutation into any gene in the rotavirus genome remains to be established. However, some progress has been achieved as discussed under Genetics and Reverse Genetics.

In vivo, the natural cell tropism for rotaviruses is the differentiated enterocyte in the small intestine, suggesting these cells express specific receptor(s) for virus attachment and entry into cells. However, extraintestinal spread of rotavirus also occurs in humans and all animal models studied,^{27,63,64-66,125,159,230,239,519,569,611,701} demonstrating a wider range of host cells than previously thought and possible additional receptors. Rotavirus replication in continuous cell cultures derived from monkey kidneys is fairly rapid, with maximal yields of virus being found after 10 to 12 hours at 37°C or 18 hours at 33°C when cells are infected at high multiplicities of infection (10 to 20 plaque-forming units [pfu]/cell).^{137,489,615} Rotavirus replication in differentiated human intestinal cell lines (Caco-2 cells) grown on permeable filter membranes is slower, with maximal yields of virus detected on the apical surface of cells 20 to 24 hours after infection.^{131,132,381} Significantly, EM studies of virus replication in polarized intestinal cells indicate that the replication process in these cells has some distinct differences from the virus replication cycle in nonpolarized cell cultures. These emerging differences are described further later.

The general features of rotavirus replication (based on studies in cultures of monkey kidney cells) are as follows:

1. Cultivation of most virus strains requires the addition of exogenous proteases to the culture medium. This ensures activation of viral infectivity by cleaving the outer capsid protein VP4.
2. Replication is totally cytoplasmic.
3. Cells do not contain enzymes to replicate dsRNA; hence, the virus must supply the necessary enzymes.
4. Transcripts function both to produce proteins and as a template for production of negative-strand RNA. Once the complementary negative strand is synthesized, it remains associated with the positive strand.
5. The dsRNA segments are formed within nascent subviral particles, and free dsRNA or free negative-stranded ssRNA is generally not found in infected cells.
6. RNA replication occurs within cytoplasmic viroplasms.
7. Subviral particles form in association with viroplasms, and these particles mature by budding through the membrane of the ER. In this process, particles acquire their outer capsid proteins.
8. Levels of intracellular calcium are important for controlling virus assembly and particle integrity.
9. Cell lysis releases particles from infected cells grown on monolayers.

In polarized intestinal cells, virus entry occurs almost exclusively through the apical membrane, although some strains enter through both the apical and basolateral membranes (see later). In addition, virus replication in polarized enterocytes alters differentiated enterocyte cell function by perturbing cellular protein trafficking, the cytoskeleton, and tight junctions, and by triggering epithelial cell signaling pathways that can activate innate responses and secretion of various chemokines or cytokines^{86,380,550} (see later). Finally, virus is released apically from polarized enterocytes by a novel, Golgi-independent, vesicular transport that does not result in extensive cytopathic effects or cell lysis.³⁸¹

FIGURE 45.8. Schematic of the rotavirus replication cycle. Major features of the rotavirus replication cycle. For details, see section on the replication cycle. Efficient replication requires cleavage of the outer capsid spike protein VP4, which allows the structurally flexible spike protein, VP4, to undergo conformational changes to interact with a series of cellular receptors. The virus is internalized by receptor-mediated endocytosis. The low calcium of the endosome releases outer capsid VP7 trimers, resulting in a conformational change in the VP4 spike protein that releases the transcriptionally active double-layered particles into the cytoplasm. Viral messenger RNAs (mRNAs) are used to translate proteins and as templates for RNA genome replication and packaging into newly made double-layered particles (DLPs) that occurs in specialized structures called viroplasm that co-localize and require components of lipid droplets for formation. Triple-layered particle (TLP) assembly is completed by a unique process involving binding of newly made DLPs to NSP4 that serves as an intracellular receptor, followed by particles budding into the endoplasmic reticulum. During this process, transient enveloped particles are seen, the outer capsid proteins VP4 and VP7 are assembled, and the transient envelope is lost. The viral glycoproteins do not traffic to the Golgi. In polarized epithelial cells, particles are released both by viral lysis and by a nonclassical vesicular transport mechanism.

Attachment

The molecular details of rotavirus adsorption, entry, and uncoating are complex and remain incompletely understood, but progress is being made because of new molecular and structural information on the outer capsid proteins and an understanding of differences in virus strains. Rotavirus attachment and entry, highlighted here primarily based on extensive structural and molecular studies using the rhesus rotavirus strain RRV, is a multistep process that involves sialic acid-containing receptors in the initial cell attachment step and coordinated interactions with multiple receptors during the postattachment steps^{31,194,450,650} (Fig. 45.8). As expected from their locations in the virus structure, VP4 and VP7 are implicated in initial inter-

actions with host cells. A broad range of cells bind rotaviruses and are infected with different efficiencies,^{133,159} suggesting that the initial binding (attachment) is a generally promiscuous interaction with a common receptor and postattachment co-receptors are critical for virus entry into the cell. Virus attachment is by VP4^{157,644} or its cleavage product VP8* on TLPs. Binding to cells does not require cleaved VP4^{138,259} or glycosylated VP7,⁵⁸⁹ but efficient cell entry requires proteolytic cleavage of VP4. Subsequent cell entry is mediated by VP5.⁸²¹

RRV and some other rotavirus strains hemagglutinate red blood cells, and neuraminidase treatment of red blood cells reduces virus binding, indicating a role of sialic acid (SA) in virus attachment.^{42,693} Neuraminidase (NA) treatment of cultured

cells reduces the infectivity of hemagglutinin (HA)-positive virus strains, SA-containing compounds such as fetuin and mucin inhibit virus binding to cells,^{406,812} and such strains are named NA sensitive.³⁶⁰ The most easily cultivatable animal rotaviruses bind SA and can infect both surfaces of polarized cells, but they preferentially infect polarized cells apically because of the presence of terminal SA.^{131,622} Many animal rotaviruses and most strains isolated from humans do not hemagglutinate RBCs, bind to and infect NA-treated cells, and are now called NA-resistant viruses¹³²; these were previously called *SA-independent viruses* but were renamed after some NA-resistant strains were shown to bind to NA-insensitive internal SA moieties on glycolipids or to modified SA moieties in oligosaccharide structures, such as those present in the GM1 ganglioside, that are resistant to NA treatment.^{179,321} NA-resistant viruses preferentially infect polarized intestinal cells through the basolateral surface.^{132,622} The consequences of efficient infection through the basolateral membrane are not fully understood, but further studies on rotavirus entry into cells likely will reveal other virus–host interactions that are relevant for pathogenesis, especially given the extraintestinal spread of virus.

VP4 is the HA based on studies of (a) reassortants showing that HA activity segregates with the rotavirus gene 4, (b) mutants that lose their HA activity are selected with VP4 monoclonal antibodies, and (c) recombinant VP4 produced in insect cells agglutinates red blood cells. X-ray crystallographic structures of RRV VP8* complexed with SA show the VP8* domain exhibits a β -sandwich fold of the galactins, a family of proteins whose natural ligands are carbohydrates, despite a lack of sequence similarity¹⁹³ (Figs. 45.4 and 45.9). The SA moiety binds within a shallow groove on the VP8* surface using residues that are conserved in SA-binding strains. The VP8* structure represents one of the first observed cases of a rotavirus protein taking on a fold seen among host proteins and, based on this structural result, it is proposed that VP4 arose from the insertion of a host carbohydrate-binding domain into a viral membrane interaction protein.¹⁹³ The structures of the VP8* core from two NA-resistant human rotaviruses (DS-1 and Wa strains) show conservation of the same galactin-like fold but exhibit other structural differences including a widening of the cleft.^{62,514} It has been suggested from NMR, infectivity assays, and modeling that such a wider cleft accommodates cellular glycans with an internal sialic acid moiety.³³⁰

Recent data indicate that at least one NA-resistant rotavirus has a narrower VP8* glycan-binding cleft that cannot bind to SA, but instead binds to a nonsialylated histo-blood group antigen.³⁴⁸ This binding may be associated with the ability of this virus to cause zoonotic infections by switching receptors; these results indicate that our understanding of rotavirus–glycan interactions remains incomplete and glycan binding may differ significantly among human rotaviruses.

The identification of cellular co-receptor(s) for rotavirus is an active area of research. Early studies and conflicting results are explained by the use of different receptors by different viruses on different cell types.^{31,194,451,650} Several integrins, including $\alpha 2\beta 1$, $\alpha \nu \beta 3$, $\alpha \nu \beta 2$, and $\alpha 4\beta 1$, are implicated as possible receptors for rotavirus cell entry, with evidence for $\alpha 2\beta 1$ being the strongest.^{153,297,323,820,822} Antibodies to these integrins or synthetic peptides that represent integrin–ligand motifs that are present in VP5* or VP7 block virus infectivity, and some integrins influence cell binding in an additive manner, sug-

gesting they may play a role in different stages of the cell entry process.³¹⁹ Neutralizing antibodies to VP5* and VP7, but not to VP8* and VP6, inhibit virus binding to integrins.²⁴⁵ Involvement of integrins at a postattachment step is consistent with observations that integrin expression increases infectivity of rotaviruses in poorly permissive cells.^{133,335} Currently, rotaviruses are characterized by their integrin usage in addition to their NA sensitivity.^{297,323,360} Integrin usage has been characterized in nonpolarized monkey kidney cells, endothelial and polarized kidney cells, and intestinal epithelial cells. Integrin and postbinding receptor usage can differ depending on the cell type(s) analyzed, and the interactions between NA-sensitive and NA-resistant rotaviruses with intestinal or extraintestinal cells are distinct and may affect the pathogenesis and outcome of infections. Integrins have a polarized distribution and are located at the basolateral plasma membrane, so this may be why NA-resistant rotaviruses preferentially infect through the basolateral surface.^{131,622} Interesting studies suggested that the addition of VP8* peptides to polarized cells can trigger the movement of basolateral proteins to the apical surface, resulting in another possible mechanism for how rotaviruses might interact with integrins.⁵³⁷ A DGE sequence in VP5* binds to the α -subunit I domain on activated $\alpha 2\beta 1$, and rotavirus binding is eliminated by mutations in activation-responsive helices of this integrin.²⁴⁴ The residues that bind to rotavirus overlap with those used by type I collagen but are distinct from those that bind echovirus 1. However, rotavirus is distinguished from collagen by its specific $\alpha 2\beta 1$ binding site requirements, and rotavirus does not activate $\alpha 2\beta 1$ or induce p38 signaling as occurs with collagen–integrin binding.²⁴⁴ Despite demonstrated binding of VP5* to integrins, the lack of signaling after this binding leaves open the question of how virus actually penetrates the membrane. VP7 is proposed to also interact with $\alpha X\beta 2$ and $\alpha \nu \beta 3$ though GPR and CNP motifs, respectively,^{297,822} but the proposed integrin-binding motif (GPR, residues 253 to 255 on VP7) is questionable because it is located on the inward-facing surface of the trimer and would not be available to interact with integrins until after uncoating.^{17,297} However, the CPN residues are potentially available for integrin binding. Evaluation of the role of integrin $\alpha 2$ and $\beta 3$ in rotavirus cell entry using RNA silencing in permissive cells also concluded that these integrins may not play a major role in the rotavirus cell entry process.³⁶² Other receptors remain to be identified as a porcine rotavirus CRW-8 does not use human or monkey $\alpha 2\beta 1$ as a cellular receptor.²⁹⁸ Thus, the crucial molecules involved in cell entry may still remain to be identified.

Heat shock cognate protein 70 (hsc70) is another putative co-receptor proposed to bind virus and mediate virus entry into cells based on experiments in which rotavirus entry is blocked by a VP5* synthetic peptide and by antibodies against human recombinant hsc70.^{318,451,584,819} The role of hsc70 is proposed based on observing enhanced virus entry into cells and subsequent enhanced virus infectivity after heating some cells at 45°C.⁴⁵⁴ Binding of purified hsc70 to two domains in VP5* as well as to a domain in VP6 are also detected in cell-free assays and may modify the conformation of virus particles to help the virus enter cells.^{313,584} To date, however, binding affinities to the proposed post-SA binding receptor molecules have not been determined, and no structures of rotavirus–protein co-receptor complexes are solved. All the implicated RV receptors on cells (GM1 ganglioside, integrin subunits, and hsc70)

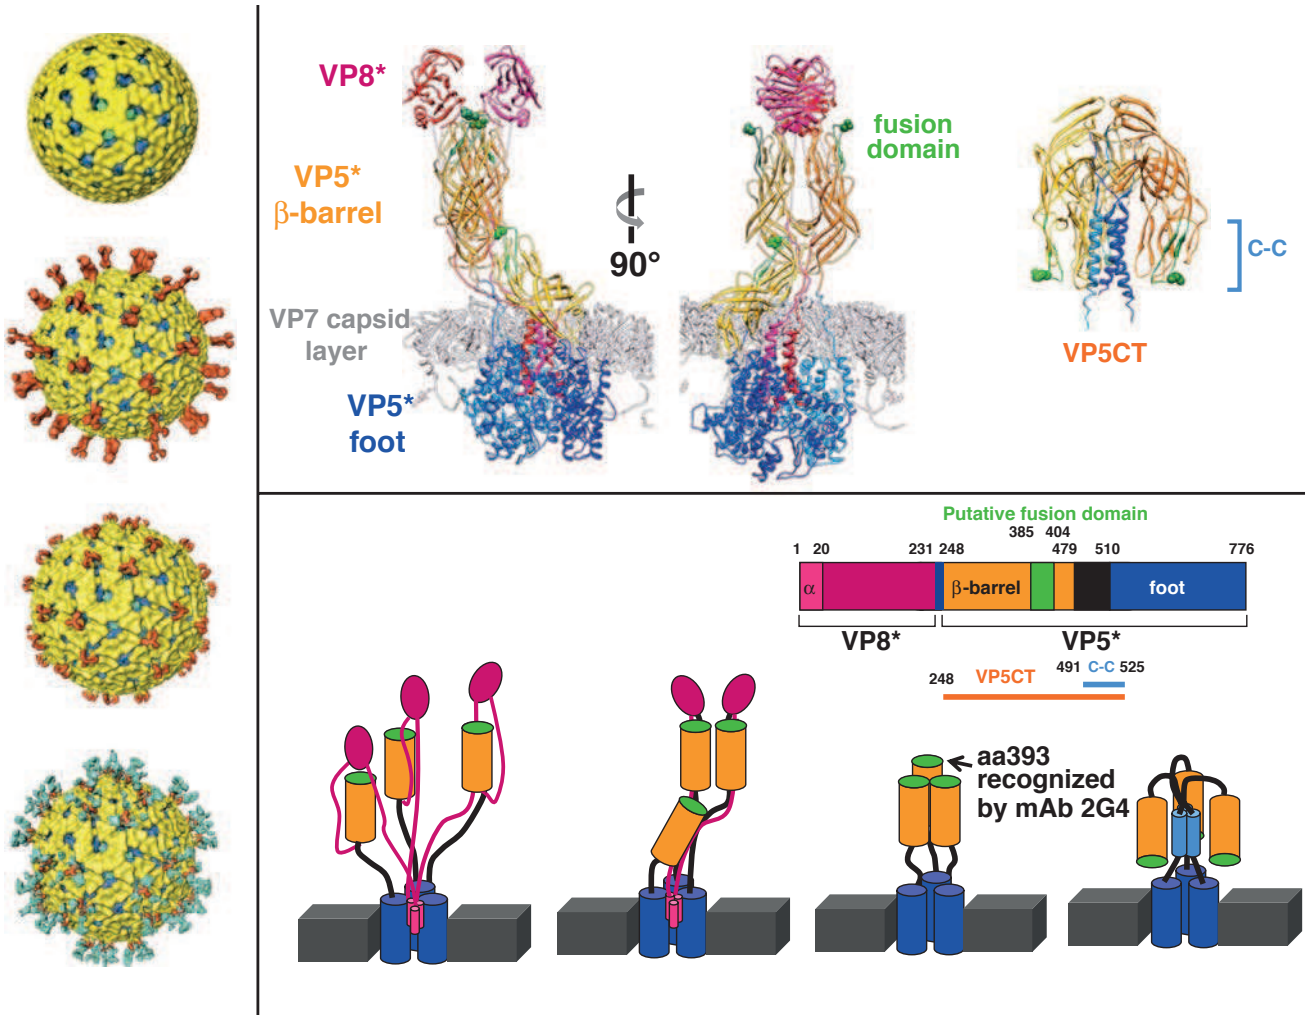

FIGURE 45.9. Conformational transitions of rotavirus particles and the spike protein VP4. **Left-side panel:** Images of cryo-electron microscopy (cryo-EM) reconstructions of rotavirus particles grown in the absence of trypsin (**top**), grown in the presence of trypsin (**second from the top**), and treated with high pH (**third from the top**), and high-pH-treated virus with a monoclonal antibody (2G4) bound to VP5* (**bottom**). Trypsin treatment causes a conformational change in the spikes and primes the cleavage products for further conformational changes. pH-treated particles provided initial evidence that the spike is a trimer and this structure may represent an intermediate that binds to co-receptors. Escape mutants indicate that mAb 2G4 binds to amino acid 393. **Top right panel:** High-resolution structures illustrating different domains and conformations of VP4. Domains in VP4 are color coded and show VP8* (magenta) and subdomains within VP5* including the β -barrel (orange), the fusion domain (green), and the foot domain (blue). The VP7 capsid layer is illustrated in gray. The mAb 2G4 binding site is indicated by green balls within the fusion domain. The **left two figures** show two orientations of an atomic structure of a trypsinized spike with dimeric and trimeric and asymmetric domains. Two of the subunits of VP5* associate to form a dimer-looking central body and the third VP5* subunit traverses the VP7 layer, forming a stalk between the body and the foot domains. Rotation of the body clearly illustrates its dimeric structure above the VP7 layer. The **right figure** shows a structure of the three color-coded domains of a cleaved form of VP5* (VP5*CT, solved from a cleaved, recombinant VP5*). These subunits associate into a coiled-coil (C-C) stabilized trimer that is shaped like an umbrella; this fold-back is thought to be the stable postmembrane penetration conformation of VP5*. **Bottom panel: Top row:** Schematic of the linear structure of VP4 showing color-coded domains. **Bottom row:** A color-coded linear diagram and cartoon representation of the proposed conformations of VP4. The colors depicted in the linear diagram correspond to the VP4 domains in the cartoon representation; VP8* (the α -helix [α] located within the foot domain [pink] and the rest of the VP8* domain [magenta]) and VP5* (the β -barrel domain [orange] containing the putative membrane fusion domain [green] and the stretch of amino acids [black] that link the β -barrel to the foot domain [blue]). The VP5*CT and coil-coil domain indicated in the panel above are indicated below the linear diagram. The numbers indicate amino acids. The cartoon represents the disordered VP4 spike on particles grown in the absence of trypsin; the ordered VP4 spike on virus grown in the presence of trypsin; the membrane-penetrating VP5* (VP8* may be retained on the particle and interact with cellular receptors but is not shown in the cartoon); and the postmembrane penetration, fold-back conformation of VP5*.

are associated with detergent-resistant lipid microdomains, and infectious rotavirus associates with these domains. Thus, lipid rafts are thought to provide a platform to facilitate efficient interaction of rotavirus receptors with virus particles.³⁶¹

Penetration and Uncoating

After initial binding to cells, rotavirus cell entry is a coordinated, multistep process involving a series of conformational changes in the capsid proteins (Figs. 45.8 and 45.9) and involves endocytic pathways. Because the initial VP8* glycan binding has a relatively low affinity, the virus entry event is probably responsible, in part, for cell type and host specificity.^{193,360,501} Crystallographic structures of VP8*–SA complexes indicate minimal conformational changes in VP8* upon SA binding,⁵¹⁴ but whether this is true in the context of the entire rotavirus structure remains to be determined. Instead, postattachment conformational changes involve VP5* and VP7.

Efficient entry of rotavirus into cells requires conformational rearrangements of the spike protein that facilitate membrane penetration. Trypsinized particles enter cells more rapidly than those not trypsinized.^{385,405} The body of the spike (VP5*) has lipophilic activity thought to be important for entry into cells,^{84,180,196,644,647,820,821} and cell permeabilization properties in the C-terminal VP5* are thought to depend on the exposure of three hydrophobic loops in the VP5* apex normally located below the VP8* lobes.⁴¹² Before trypsin cleavage, VP4 is flexible and spikes are not visible by cryo-EM, although they are present on particles¹⁵⁸ (Fig. 45.9). Trypsinization of VP4 stabilizes the spike structure, inducing an initial disorder-to-order or flexible form-to-rigid spike transition that results in a unique, elongated, asymmetrical shape and primes VP4 for additional conformational changes¹⁵⁸ (Fig. 45.9). Exposure of the specific cleavage site in the asymmetric spike structure and masking of nonspecific trypsin sites in VP4 by VP7 regulates the cleavage of VP4.⁶⁷⁵ The trypsin-primed VP4 intermediate is held within the particle and ready to undergo further molecular rearrangements during virus entry into cells that includes promoting membrane permeability associated with virus entry.⁶⁷⁵ The 3.2-Å crystal structure of the main part of the VP5* stalk generated *in vitro* reveals a folded-back rearrangement that translocates three clustered hydrophobic loops from one end of the molecule to the other to form a coiled-coil stabilized trimer that is shaped like an umbrella; this fold-back form is thought to be the stable “postpenetration” conformation of VP5*¹⁹² (Fig. 45.9). An entry-associated event, proposed to be dissociation of VP7 by exposure to low calcium levels in the endosome, triggers the transition of the trypsin-primed VP5* spike to the fold-back trimeric umbrella conformation that interacts with the uncoating membrane and refolds to destabilize the membrane.^{192,514,805} The VP5* fold-back depends on both membrane interactions and virus uncoating, suggesting that this rearrangement is one of the final steps of RV entry.^{732,805}

Studies with pH treatment of a NA-sensitive virus provide support for this proposal.^{192,514,586,587,805} At elevated pH, the spike undergoes a dramatic irreversible conformational change and becomes stunted with a pronounced trilobed appearance, although the amount of VP4 on particles remains unchanged (Fig. 45.9). Three Fab fragments of the VP5*-specific mAb, 2G4, can then bind to these altered spikes, indicating that VP4 has undergone a dimer-to-trimer transition (Fig. 45.9). Particles with altered spikes no longer hemagglutinate red

blood cells or infect mammalian cells. They retain the ability to bind to mammalian cells, but in an NA-resistant manner, different from untreated particles that bind cells in an NA-sensitive manner. High-pH treatment may trigger a conformational change that mimics the transition in VP4 that occurs with the post-SA attachment step. These particles resemble a mutant virus of an NA-sensitive rhesus rotavirus that exhibits NA-resistant cell binding, in contrast to its parental strain, and attaches to cells by interacting with the integrin $\alpha 2\beta 1$ through a DGE motif in VP5*.⁸²⁰ Of interest, the conformational rearrangements of VP5* translocate this DGE motif to the external surface of the trypsin-primed structural forms of VP5*, making it accessible to bind to an integrin.⁸⁰⁵ Recent analysis of integrin binding of virus strains with distinct VP5* sequences has identified sequence variation in VP5* amino acids that parallel rotavirus strain-specific differences in the effects of virus binding to the $\alpha 2$ I domain. These results indicate VP5* amino acids 335 to 380 that are surface exposed and near the DGE sequence may also influence rotavirus recognition of $\alpha 2\beta 1$ in addition to the DGE site.²⁴⁴

Internalization does not take place at 0°C to 4°C, indicating that this step requires active cellular processes.^{406,590} All virus is internalized by 60 to 90 minutes after binding.⁴⁰⁶ The mechanism of internalization (penetration) into cells remains unclear. Both morphologic and biochemical approaches have been used to investigate the mode of entry of rotaviruses into cells, and both receptor-mediated endocytosis and direct membrane penetration have been suggested as mechanisms of rotavirus entry into cells; trypsin-treated and non-trypsin-treated virus may enter cells by different mechanisms as reviewed previously.²¹⁵ Recent studies indicate that different rotavirus strains enter cells through different endocytic pathways.³²³

Other viruses that initiate infection by mechanisms involving receptor-mediated endocytosis often depend on the acidification of endosomes for partial uncoating or entry into the cell. The importance of acidification of endosomes for the initiation of infection of rotaviruses has been studied by several groups.^{260,385,405,462,791} In all cases, lysosomotropic agents (ammonium chloride, chloroquine, methylamine, and amantadine) do not affect rotavirus entry. Energy inhibitors (sodium azide and dinitrophenol) have a minimal effect on rotavirus infection, and this has been taken to suggest that rotaviruses do not use endocytosis to enter cells. Other endocytosis inhibitors, such as dansylcadaverine and cytochalasin D, and in some, but not all, cases the vacuolar proton-adenosine triphosphatase (ATPase) inhibitor bafilomycin A1, also do not block rotavirus entry. These results indicate that neither endocytosis nor an intraendosomal acidic pH or a proton gradient is required for rotavirus entry into cells.

While the passage of rotaviruses from endocytic vesicles to the cytoplasm does not occur by a pH-dependent fusion mechanism, other data indicate that rotaviruses are still taken up by endocytosis. Direct demonstration of virus fusion with membranes or hemolysis is lacking. Protease cleavage of VP4 is important for rapid entry into cells, and particles containing cleaved VP4 possess lipophilic activity and can affect release of fluorescent dyes from liposomes and isolated membrane vesicles. Rotavirus entry into cells can also be monitored by co-entry of toxins, such as α -sarcin, into cells^{162,446} and by a cell-to-cell fusion from without assay.^{207,227} Most observations are consistent with the hypothesis that virus enters cells by

endocytoses after direct interactions with a series of receptors on the plasma membrane.^{535,647}

The outer capsid proteins of rotavirus that are solubilized from virus particles are able to permeabilize cellular membranes,⁶⁴⁶ and it has been proposed that the outer capsid proteins are solubilized within an endocytic vesicle because of low Ca^{2+} concentrations. The decrease in calcium concentrations within the endosomal vesicle might trigger conformational changes in the capsid, capsid solubilization, and vesicle lysis.⁶⁴⁶ In this Ca^{2+} -dependent endocytosis model, acidification of the endosome would not be needed for the infectious process. Use of the calcium ionophore A23187 to increase the intracellular Ca^{2+} concentration during the early stages of replication can block uncoating.⁴⁶² These results support the hypothesis that low Ca^{2+} concentrations in the intracellular microenvironment may be responsible for uncoating. This idea was originally proposed because it was known that removal of the outer capsid of particles and activation of the endogenous polymerase could be accomplished by calcium chelation.^{143,341}

It is also possible that more than one mechanism, including endocytosis and direct entry, is operative for rotaviruses, as has been proposed for polioviruses and reoviruses.^{68,189} Further studies are needed to determine whether the common endocytosis-mediated entry pathway exists for all rotaviruses and in all cell types. Studies with drugs and dominant-negative mutants suggest that virus enters cells through a non-clathrin-, non-caveolin-dependent mechanism that depends on the presence of cholesterol on the cell membrane and on a functional dynamin.⁶⁵⁹ Trypsin also has been detected associated with the rotavirus outer capsid and is activated by solubilization of the outer capsid proteins.⁴³ This activated trypsin is proposed to cleave VP7 and VP4 into fragments capable of disrupting membranes, and this may allow DLPs to gain access to the cytoplasm to begin actively transcribing viral mRNA to complete the next step in the viral life cycle.

The entry of RRV, which is NA sensitive and binds to $\alpha 2\beta 1$ and of $\alpha \nu \beta 3$ integrins and hsp70, is the most extensively studied by biochemical, structural, and molecular methods. RRV entry into polarized cells is through an endocytic pathway but reportedly does not require cholesterol or a functional dynamin.⁷⁹¹ Use of imaging and unique mAbs that detect regional or conformation-dependent epitopes on VP8* and VP5* or soluble, unassembled protein to follow the proteins on incoming RRV particles at very early time points prior to the onset of viral replication indicates that internalization and decapsidation occur directly after cell membrane penetration as assessed by disappearance of trimeric VP7.⁷⁹¹ In addition, virus entry into cells involves endocytosis, calcium-dependent uncoating, and several VP4 conformational changes; VP8* staining is lost at the time of cell penetration and is not found in the cytoplasm, while VP5* is detected in the cytoplasm within 1 hour of infection. The fold-back conformation of VP5* is only detectable at the entry step.⁷⁹¹ VP5* and VP7 co-localize with early endosome markers Rab4 and 5, indicating RRV uses an endocytic route limited to the early endosomes to enter cells. Bafilomycin A1 and concanamycin A, two pharmacologic inhibitors of the vacuolar-type H^+ -ATPase, reduced cytoplasmic staining of VP6 indicative of blocking entry and reduced the appearance of the folded-back VP5*, suggesting that the appearance of this epitope is specific to entry. Elevating endosomal Ca^{2+} concentration also blocked entry. This study supports a model of RRV entry in which, after

membrane binding and internalization, the low Ca^{2+} concentration in the endosome triggers VP7 decapsidation and the appearance of the VP5* fold-back, ultimately leading to the release of DLPs into the cell cytoplasm. The results also suggest that the primary effect of BafA1 on RRV infection is mediated indirectly through changes in the endosomal Ca^{2+} gradient.⁷⁹¹ Unexpectedly, these studies did not find a role for dynamin or cholesterol in RRV entry, which had been implicated in RRV entry into nonpolarized cells through a non-clathrin-, non-caveolin-mediated endocytosis pathway that depends on a functional dynamin and on the presence of cholesterol on the cell surface.^{323,659} Entry of other RV strains with different NA sensitivity and integrin dependence into MA104 cells is reported to be dependent on hsc70, dynamin, and cholesterol, but these distinct strains enter cells through clathrin-mediated endocytosis pathways.³²³ The reasons for these differences are not known but might result from the different virus strains or the heterogeneity of raft-type membrane microdomains on different cell types in different differentiation states.¹⁷⁷

RNA Synthesis Overview

Incoming RV particles containing the dsRNA genome segments must synthesize mRNAs that direct the synthesis of viral proteins and also serve as templates for the synthesis of the dsRNA genome that becomes encapsidated into newly made particles. The virion polymerase performs these functions as a transcriptase and as a replicase at different times during the replication cycle. Synthesis of viral transcripts is mediated by the endogenous viral RNA-dependent RNA polymerase complex (PC), consisting of VP1 and VP3, which is latent in the virion, where it appears as a flower-shaped feature in the icosahedrally averaged cryo-EM reconstruction of the virion attached to the inner surface of the VP2 layer at all the fivefold axes (Fig. 45.4). The PC contains the enzymatic activities needed for synthesis of capped messenger RNA, including transcriptase, nucleotide phosphohydrolase, guanylyltransferase, and methylases. Each genome segment is transcribed simultaneously and repeatedly by a specific polymerase complex within the confines of the capsid architecture, and the resulting transcripts exit through the type I channel system at the axis adjacent to its site of synthesis. This mechanism of transcription offers an explanation of why no dsRNA virus contains more than 12 genome segments.

The PC must be activated for transcription to occur. Transcription begins following removal of the VP7 outer layer and can also be studied *in vitro* by treatment of TLPs with a chelating agent or by heat shock treatment that removes the outer capsid proteins.^{143,694} Transcribing particles will continuously synthesize milligram quantities of mRNAs *in vitro* as long as fresh precursors and an energy-generating system are provided. Rotavirus transcription requires a hydrolyzable form of adenosine triphosphate (ATP). Studies with analogs that inhibit transcription suggest that ATP is required in reactions other than polymerization⁶⁹⁴ and may be used for initiation or elongation of RNA molecules.

Ultimately, transcription must be inhibited to allow RNA replication to proceed and virus assembly to be completed. While not completely understood, transcription can be inhibited by several mechanisms. Cryo-EM studies of DLPs complexed with

some monoclonal antibodies to VP6, or the addition of VP7 onto DLPs, indicate a conformational change at the interface of the VP2–VP6 layers or in the VP6 trimers can inhibit sustained elongation and translocation of transcripts.^{235,435,723} It is also possible that binding of VP6 to NSP4, which serves as an intracellular receptor for particle assembly (see later), is the key interaction that inhibits transcription. This hypothesis is consistent with the observation that knockdown of NSP4 by siRNA increases viral mRNA synthesis.⁶⁸⁴ NSP4 can form concentration-dependent pentamers, and such structures in the ER may interact with VP6 molecules by a fivefold axis on the surface of the DLPs.¹⁰⁶

The structure of the polymerase must provide mechanisms for transcription and subsequent RNA replication where the minus-strand RNA as well as duplex formation is achieved to produce new infectious virions. Transcription to produce (+) mRNAs requires several functions, including unwinding the genomic dsRNA, entry of the (–)RNA templates for synthesis

of nascent (+)RNA, exit of the (–)RNA for subsequent annealing and further rounds of transcription, and exit of the nascent (+)RNA for capping and extrusion from the DLP. In the replication mode, the polymerase must provide a mechanism for entry of (+)RNA template and exit of the duplex. There also should be easy access for the NTPs into the catalytic center of VP1 for (–)RNA synthesis.

The Viral RNA Polymerase, (+) Strand, and (–) Strand RNA Synthesis

Insight into how the rotavirus polymerase mediates both transcription and replication is now available based on the structure of VP1.⁴⁶⁰ VP1 has a compact cage-like structure with three domains similar to that of the reovirus polymerase.⁷⁰⁹ VP1 contains a putative cap-binding site to anchor the capped 5' end of the (+)RNA, and the structure has four distinct tunnels that lead to the central catalytic core of VP1 (Fig. 45.10). Having a

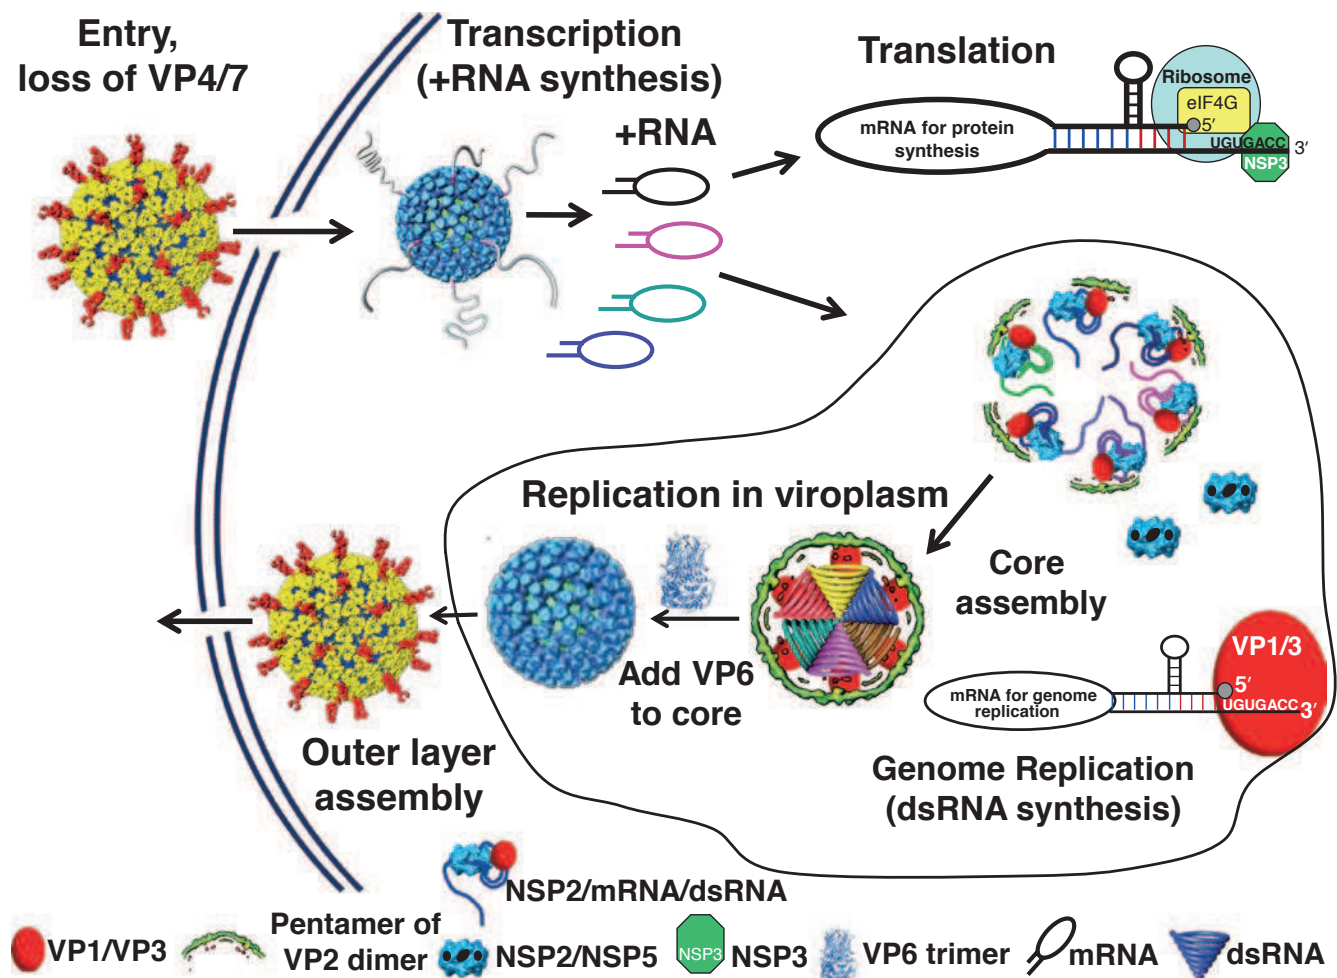

FIGURE 45.10. Virion disassembly and functions of RNAs for transcription, translation, genome replication, and packaging.

With virus entry into cells, the double-layered particles (DLPs) lose the outer layer proteins and the DLPs become transcriptionally active and release (+)RNAs that are thought to form panhandle structures that are translated into viral proteins and replicated into genomic double-stranded RNA (dsRNA) in viroplasms. A pentamer of VP2 dimers and VP1/VP3 form the initial assembly unit. NSP2 is likely involved in feeding (+)RNA into the enzyme complex for (–)RNA synthesis and formation of the duplex RNA.³²⁰ Twelve such units assemble together to encapsidate the genome segments to form the virion core, which subsequently is coated with VP6 to make new DLPs. (Modified from Hu L, Crawford SE, Estes MK, et al. 2010. Rotavirus structure and functional implications. In Hein NT, Baldacci G, Haenni AL, Benedetti EL, eds. *Viruses Responsible for Emerging Diseases in South-East Asia*, Universite Paris Diderot-Paris 7, 2011.)

fourth tunnel, a distinction from other known RNA-dependent RNA polymerases, is needed for the exit site of the (+)RNA transcripts. Based on information from reovirus polymerase-RNA elongation complexes,⁷⁰⁹ the four distinct tunnels in VP1 are implicated in (a) the entry of the templates ([+]RNA or [-]RNA), (b) the entry of NTPs, (c) the exit of dsRNA/(-)RNA, and (d) the exit of the (+)RNA. Having two distinct product exit tunnels ensures that (+)RNAs are effectively shuttled out of the core, while nascent dsRNA gene segments are directed toward the particle interior. In addition, the (-)RNA exits proximal to the template entry tunnel, which should facilitate its reuse in subsequent rounds of (+)RNA synthesis. Finally, the exiting of the (-)RNA template and (+)RNA product of transcription through separate tunnels suggests that the capping enzyme and polymerase are capable of internally separating dsRNA duplexes.

Crystallographic structures of VP1 in complex with the consensus sequences (CSs) in the 3' end of the minus strand (template for [+]RNA synthesis) and in the 3' end of the (+)RNA (template for [-]RNA synthesis) are also available.⁴⁶⁰ These structures indicate that for transcription, sequence-specific recognition of the 3' CS of the minus strand for positive-strand synthesis is not critical as it takes place within the confines of the capsid.⁴⁶⁰ In contrast, sequence-specific interactions are made only with the 3' CS of the plus strand that is anchored to the template entry site in VP1. This sequence-specific interaction involving the UGUG motif in the 3' CS (+)RNA confirms biochemical studies that showed this motif is the polymerase recognition signal and is required for high-affinity interactions with VP1 and subsequent replicase activity.^{112,115,116} Of interest, the VP1 3' CS (+)RNA complex structure is in an auto-inhibited state with a single nucleotide at the 3' end overshooting the initiation register. For VP1 to initiate (-)RNA synthesis, the overshoot 3' end of the template must be realigned, a priming loop must be repositioned to allow binding of the priming nucleotide, and a plug formed from the C-terminal domain of the polymerase that is in the dsRNA exit tunnel must be dislodged. These conformational changes in VP1 require VP2, GTP, the template, and Mg²⁺. Interactions with VP2 are known based on biochemical studies showing that interaction of RNA with VP2 is necessary for the initiation of rotavirus genome replication,^{576,824} but the details of how VP2 interacts with VP1 and how this interaction activates VP1 to initiate genome replication remain to be understood. They may require interactions with other viral proteins within assembling replication intermediates. Genome replication, RNA assortment and encapsidation, and particle assembly are highly coordinated events.

Kinetics and Cellular Sites of Transcription and Replication

Transcription in cells occurs following the release of DLPs from the endosome. Consistent with this idea, cells are susceptible to infection by liposome-mediated transfection of DLPs, indicating that simple delivery of these particles into the cell cytoplasm permits transcription to proceed.⁴¹ Transcription is asymmetric, and all transcripts are full-length positive strands made off the dsRNA negative strand.⁴⁹⁰ Primary transcription must occur before RNA replication. The synthesis of negative-strand RNA occurs in perinuclear nonmembranous, electron-dense cytoplasmic inclusions known as *viroplasm*s (see later),

concurrently with the packaging of positive-strand RNA into core replication intermediate (RI) particles.^{26,683}

The kinetics of synthesis of positive- and negative-stranded RNAs has been studied in rotavirus-infected cells,⁶⁹⁷ in a cell-free system using extracts from infected cells,⁵⁷⁰ in an electrophoretic system that allows separation of the positive and negative strands of rotavirus RNAs in acid urea agarose gels,^{571,575} and by quantitative RT-PCR.²⁶ Positive- and negative-stranded RNAs are initially detected during the first 4 hours after infection.^{26,697} A small linear increment of plus- and minus-strand RNA synthesis is detected followed by a logarithmic increase at later times of infection. This quantitation indicates that the entering DLPs produce a small amount of mRNA, which is then translated and replicated, producing new DLPs. When new DLPs are assembled, these particles then transcribe their genomes, initiating a secondary wave of transcription that significantly increases the amount of viral mRNA and dsRNA. Newly assembled DLPs are required for this second wave of transcription as knock-down of any of the viral proteins that constitute the DLP (VP1, VP2, VP3, and VP6) ablates the logarithmic increase in RNA synthesis.²⁶ The amount of mRNA accumulated at late time points postinfection is significantly greater (at least six times more) than the dsRNA accumulated during the same period of time. The assembly of infectious virus particles parallels the replication of the viral genome.

Viroplasms, the sites of incorporation of (+)RNA into replication intermediates and virus assembly, first appear 2 to 3 hours after infection. The number of viroplasms initially increases and then decreases with time after infection, whereas the area of each viroplasm increases, suggesting fusions of viroplasms.^{204,226} Viroplasms contain viral proteins (VP1, VP2, VP3, VP6, NSP2, NSP5, and in some strains NSP6).^{287,591,592,628} NSP2 and NSP5 are major components of viroplasms, and expression of these two proteins alone is sufficient to induce the formation of *empty* viroplasm-like structures. Viroplasm nucleation may be due to NSP2-tubulin interactions as NSP2 sequesters free tubulin molecules and induces microtubule depolymerization in RV-infected cells.⁴⁷⁴ Microtubules also may play a role in the growth and fusion of viroplasms later in infection based on inhibition of these processes by nocodazole.⁹⁵ Viroplasms associate with lipids and proteins (perilipin, adipocyte differentiation-related protein [ADRP]) characteristic of cytoplasmic lipid droplets (LDs), and blocking or interfering with LD formation reduces the number of functional viroplasms and production of infectious virus.¹²² The proteasome is also essential for early assembly of viroplasms.^{147,456} Inhibition of proteasome activity following virus entry and uncoating reduces accumulation of virus proteins, viroplasm formation, and RNA replication. The requirements of LDs and proteasomes for viroplasm formation represent examples of a virus hijacking cellular pathways for its own replication, and further information of how RV proteins interact or regulate these pathways should help understand the early stages of viroplasm formation and particle assembly.

The key role of NSP2 and NSP5 in viroplasm functions of genome replication and packaging has been demonstrated by studies of temperature-sensitive mutants or knocking down the expression of NSP2 or NSP5 by RNA interference or antibody treatment, which results in inhibition of viroplasm formation, genome replication, virion assembly, and a general decrease of viral protein synthesis.^{96,455,619,684,714,744}

NSP2 is an essential multifunctional protein with sequence-independent ssRNA binding as well as enzymatic activities including nucleoside triphosphatase (NTPase), nucleoside diphosphate (NDP) kinase,⁴²⁸ RNA triphosphatase (RTPase),⁷⁴⁵ and nucleic acid helix destabilizing activities.^{710,711} NSP2 is the most abundant protein of viroplasms,⁵⁹² is essential for viroplasm formation,⁶¹⁹ and exists as an octamer. The monomeric subunit has two distinct domains separated by a deep, catalytic cleft. The association of monomers results in a doughnut-shaped octamer with a 35-Å central hole along the fourfold axis and grooves that run diagonally across the twofold axes and are lined by basic residues³⁷⁰ (Fig. 45.11). The C-terminal domain of NSP2 resembles the cellular histidine triad (HIT) family of proteins that hydrolyze nucleotides. The NTP-binding residues are located within the cleft between the two domains.¹⁰⁰ Mutation of the catalytic residue (H225A) abrogates hydrolysis of the γ -phosphate from the 5' end of RNA and dsRNA synthesis.^{712,746} Although the NTPase activity is

localized in the monomeric subunit, the ability to bind RNA and other proteins requires the formation of the octamer.⁷⁴⁶ Cryo-EM structures of NSP2 octamer complexes show that both ssRNA and NSP5 (the other key component required for viroplasm formation) share the same binding site, the grooves in the NSP2 octamer, and NSP5 competes with ssRNA binding.³⁷⁶ Tubulin also binds to these charged grooves.⁴⁷⁵ In virus-infected cells, NSP2 is associated with polymerase complexes, including VP1 and VP2 and partially replicated viral RNA.¹⁸ Taken together, these results indicate that NSP2 is critical for RNA replication and suggest that competitive binding of different ligands to the groove may regulate NSP2 function during genome replication and virus assembly (Fig. 45.11).

NSP5 is a dimeric phosphoprotein rich in Ser and Thr residues that undergoes O-linked glycosylation,^{6,601,785} as well as phosphorylation that occurs when NSP5 is co-expressed with VP2.¹⁴⁶ NSP5 reportedly exists in several oligomeric forms, and biophysical and structural analyses suggest that the

FIGURE 45.11. Structures of NSP2 and interactions with RNA and NSP5. **Left:** Octameric structure of NSP2. The N- and C-terminal domains of two subunits are colored green and red, respectively, and the rest of the subunits in the functional octamer are shown in gray. The donut-shaped octamer is viewed along the fourfold axis (**top left**) and along one of the two twofold axes perpendicular to the groove lined by positively charged residues (**bottom left**).³⁷⁰ **Middle:** NSP2 monomer showing the two subunits and catalytic cleft indicated by arrow. **Right:** Cryo-electron microscopy (cryo-EM) reconstruction of NSP2 binding to NSP5 (**top** with NSP5 in blue) and NSP2 binding to RNA (**bottom** with RNA in green) viewed perpendicular to the groove. These two ligands both bind to the grooves of the NSP2 octamer. (From Jiang et al.³⁷⁶ Cryoelectron microscopy structures of rotavirus NSP2-NSP5 and NSP2-RNA complexes: implications for genome replication. *J Virol* 2006;80:10829–10835.)

biologically relevant form in cells required for viroplasm formation is a decamer.⁴⁷⁵ The self-association of NSP5 may be regulated by NSP6, which is encoded by an alternative reading frame of gene segment 11 in most virus strains and is also associated with viroplasms.⁷²⁹ The precise roles of the modifications in NSP5 function remain unknown. However, the formation of viroplasm-like structures is also calcium regulated, and a pseudo-EF-hand motif in NSP5 (DxDxD) located upstream of a C-terminal helical domain possibly triggers calcium-dependent viroplasm formation.⁶⁷² Although NSP5 binds to the grooves in NSP2, steric hindrance is proposed to prevent NSP2 from binding to all NSP5 promoters, and therefore, some NSP2 is thought to remain free to interact with other binding partners such as viral RNAs and the viral polymerase to perform functions other than viroplasm organization.⁴⁷⁵

Viroplasm maturation and function also require NSP4, the only nonstructural protein that does not bind RNA. Based on siRNA experiments that knocked down NSP4 expression, NSP4 plays a role in the intracellular accumulation and the cellular distribution of several viral proteins, influencing the development of viroplasms, linking genome packaging with particle assembly, and acting as a modulator of viral transcription.^{453,684} A vesicular form of NSP4 is modulated by the levels of intracellular calcium, and that NSP4 also forms caps on viroplasms and co-localizes with the autophagy protein LC3.⁴⁴ Precisely how NSP4 regulates RNA synthesis remains to be determined. Formation of the punctate vesicular structures requires the elevation of cytoplasmic calcium (Ca^{2+} cyto), which is mediated by NSP4 functioning as a viroporin in the ER membrane.³⁵⁶ NSP4 regulation of Ca^{2+} cyto may serve as a viroplasm assembly trigger that directs NSP5 to form viroplasms during viral infection, and later NSP4 binding to VP6 functions to inhibit polymerase activity, leading to a switch to complete genome replication and encapsidation.

Genomic RNA Replication and Encapsidation (Packaging)

After its synthesis, dsRNA remains associated with subviral particles, suggesting that free dsRNA is not found in cells. Because of its inherent stiffness,³⁸⁷ dsRNA is not packaged. Instead, (+)RNAs are assorted, replicated, and packaged within complexes that remain poorly understood, but subviral particles (complexes separable by sedimentation through sucrose gradients and by equilibrium centrifugation in CsCl gradients) in which dsRNA synthesis occurs have been characterized both in infected cells and in a cell-free system. Based on structural and biochemical studies, a model of rotavirus replication includes genome encapsidation and DLP assembly occurring concurrently with the formation of a replication intermediate composed of a pentamer of VP2 interacting with VP1 and VP3.^{488,585,586} In this model, 12 units each composed of pentamers of VP2 dimers, a VP1/VP3 complex, and a dsRNA segment associate to form the VP2 capsid layer, which provides a platform for the subsequent addition of VP6 trimers resulting in the formation of the DLP. Protein components in these units perhaps represent the replication complex in which the (+)RNA, brought in with the aid of NSP2/NSP5, is fed into the enzyme complex for (–)RNA synthesis and the formation of the duplex RNA, which is spooled around the enzyme complex. VP2 may interact with NSP5⁴⁹ and NSP5 with the NSP2 octamer. This multimeric complex would then provide a platform or scaffold for

the replication complex.³⁶⁹ The NSP2 octamer binds (+)RNA and mediates unwinding of the RNA secondary structure via its nucleic acid helix destabilizing activity. The NSP2 octamer also binds the viral polymerase VP1 and may feed unwound RNA to the polymerase.⁴⁰⁵ The octamer is also an NTPase, but how this activity is used in rotavirus genome replication remains unclear. Structural studies to investigate how NSP2 interacts with nucleotides and hydrolyzes NTP indicate that the NTPase activity of NSP2 is associated with a phosphoryl-transfer function similar to that seen for cellular nucleoside diphosphate kinases. This kinase-like activity of NSP2 may have a role in the homeostasis of nucleotide pools within the viroplasm during genome replication.⁴²⁸ Overall, VP1 replicates the RNA, and the (–)RNA exits VP1 and interacts with an octamer of NSP2 so that NSP2, functioning as an RTPase, cleaves the γ -phosphate from the 5' (–)RNA.⁷⁴⁵ This accounts for the absence of the γ -phosphate at the 5' end of the double-stranded genomic RNA.^{359,490} However, how NSP2 recognizes the 5' CS of the (–)RNA of the dsRNA products exiting from VP1 is not understood, and this knowledge may be important to understand how NSP2 may play a role in facilitating genome packaging.

The selective packaging mechanism that leads to the presence of equimolar genome segments within rotaviruses, or any of the other members of the family *Reoviridae*, remains a challenging puzzle. Several models have been proposed.^{574,586} A currently favored model proposed earlier is based on structural data indicating that the core represents a collection of functionally separate pentameric units, with each unit containing its own RNA-dependent RNA polymerase activity and capping enzyme complex and being responsible for transcription of one of the genome segments.⁴³³ In this model, encapsidation would be concurrent with capsid assembly, and each VP1–VP3 enzymatic complex would associate with a specific mRNA and attract the VP2 core protein and assemble into pentamers (Fig. 45.12). RNA–RNA interactions between the mRNA of the distinct pentameric units would then drive the assembly of the icosahedral core from the pentameric units. Structural changes in the core lattice protein VP2, as a consequence of pentamer–pentamer binding, may activate the RNA-dependent RNA polymerase and stimulate negative-stranded RNA synthesis to form the genome. Another model, based on the ability of the rotavirus capsid proteins to self-assemble into empty VLPs^{157,431} and on data on the dsRNA bacteriophage phi6,⁵¹⁰ suggests that empty cores are first made and that mRNAs would be replicated and subsequently inserted into these cores. Future work will determine which of these models, if any, may be correct.

Virion Maturation

A distinctive feature of rotavirus morphogenesis is that subviral particles, which assemble in the cytoplasmic viroplasms, bud through the membrane of the ER, and maturing particles are transiently enveloped (Fig. 45.8). This is one of the most interesting aspects of rotavirus replication, differing from members of other genera in the family *Reoviridae* and from any other virus. The envelope acquired in this process is lost as particles move toward the interior of the ER, and the envelope is replaced by a thin layer of protein that ultimately constitutes the outer capsid of mature virions. Rotavirus particle transport, maturation, and assembly remain an interesting model to understand the transport of protein complexes across the ER membrane as well as envelope particle formation.

FIGURE 45.12. Structural features of VP1 polymerase. On the **left**, the structure of VP1 in complex with RNA oligonucleotide is shown.⁴⁶⁰ Ribbon diagram of VP1/RNA complex (PDB ID: 2R7R) is shown on the **left**. The N-terminal domain is in yellow, the C-terminal domain is in magenta, and the C-terminal plug is in cyan. The subdomains of the polymerase domain are in light blue (fingers), red (palm), and green (thumb). On the **right** is a cutaway of the surface rendering of the complex showing the four tunnels extending into the central cavity, the catalytic center.

Morphologic and biochemical data are consistent with rapidly assembling DLPs serving as an intermediate stage in the formation of triple-layered virions. The sites and precise details of RNA replication are beginning to be understood, and the viroplasms are the sites of synthesis of the double-layered particles that contain RNA (see earlier). This conclusion is based on the localization of several of the viral proteins (VP2, NSP2, NSP5, NSP6) to viroplasms, and of VP4 and VP6 to the space between the periphery of the viroplasm and the outside of the ER,^{287,591} and on the observation that particles emerging from these viroplasms bud directly into the ER that contains the glycoproteins VP7 and NSP4.

A fraction of VP4 can be detected in a filamentous array²⁸⁷ and at the plasma membrane associated with microtubules.^{178,538} Although the function of VP4 in lipid rafts at the plasma membrane in viral morphogenesis remains unclear, it has been proposed that VP4 is added to particles as an extra-ER event.¹⁷⁸ Particles lacking VP4 can be formed in cells treated with siRNA to gene 4, suggesting that VP4 is not essential for assembly or for release of DLPs from the ER.¹⁷⁶ Infectious particles are found associated with lipid rafts at the cell surface.^{163,165,361,664} Silencing VP4 and NSP4 (but not VP7) reduces rotavirus-raft interaction associations apparently by reducing targeting of VP4 to the rafts; these results support the idea that the primary association of VP4 with rafts occurs during the initial stages of particle assembly in the ER.¹⁶³ Taken together, two pools of VP4 appear to exist, with one associating with particles in the ER and one being found independently at the plasma membrane.

In the ER of SA11-infected cells, two pools of VP7 exist that can be distinguished using two classes of antibodies.³⁸⁴ One pool, found only on intact particles, is detected only by a neutralizing mAb. The second pool of VP7 is unassembled, remains associated with the ER membrane, and is detected by a polyclonal antibody made to denatured VP7.³⁸⁴ Distinction of these two forms of VP7 permitted a kinetic study of the assembly of VP7 and of other structural proteins into particles. The incorporation of the inner capsid proteins into double-

layered particles was found to occur rapidly, whereas VP4 and VP7 appear in mature TLPs with a lag time of 10 to 15 minutes. Kinetic analyses of the processing of the oligosaccharides on the two pools of VP7 show that the virus-associated VP7 oligosaccharides have a 15-minute lag compared with that of the membrane-associated form, suggesting that the latter is the precursor to virion VP7. This lag appears to represent the time required for virus budding and outer capsid assembly.³⁸⁴

NSP4 plays a key role in the assembly of TLPs. NSP4 is the only nonstructural protein that does not bind to RNA. NSP4 has been studied extensively because it plays a role in viral morphogenesis and functions as an enterotoxin (see later). NSP4 has multiple domains and an increasing number of functions.^{32,215} NSP4 is a 20K primary translation product; it is co-translationally glycosylated to become a 29K species, and oligosaccharide processing yields the mature 28K protein that is a transmembrane protein of the ER.^{209,383} The 175-aa polypeptide backbone of NSP4 consists of an uncleaved signal sequence, three hydrophobic domains with two N-linked high mannose glycosylation sites being in the first hydrophobic domain, a predicted amphipathic α -helix (AAH) that overlaps a folded coiled-coil region, the H2 transmembrane domain that traverses the ER bilayer, and the C-terminus, which is hydrophilic and forms an extended cytoplasmic domain.^{71,108,210,383} The carbohydrate moieties remain sensitive to endoglycosidase H digestion, and processing of the Man9-GlcNAc carbohydrate added to NSP4 stops at Man8GlcNAc with the mannose-9 species predominating,^{71,383} indicating that no further trimming occurs in the Golgi apparatus.

The C-terminal cytoplasmic domain (aa 161 to 175) of NSP4 functions in viral morphogenesis by acting as an intracellular receptor on the ER membrane.^{24,718,719} NSP4 binds newly made DLPs and mediates the budding of these particles into the ER lumen (see later). A receptor role for NSP4 is supported by the observation that DLPs bind to ER membranes containing only NSP4.^{23,24,502} The AAH region, distinct from the receptor domain, is predicted to adopt an α -helical coiled-coil structure

and is thought to mediate oligomerization of the virus-binding domains into a homotetramer.⁷²⁰ A crystal structure of the oligomerization domain of NSP4, which spans aa residues 95 to 137 (NSP4 95 to 137), self-associates into a homotetrameric coiled-coil, with the hydrophobic core interrupted by three polar layers and two of the four Glu120 residues coordinating a divalent cation⁷² (Fig. 45.11). Recently, crystallization of a similar domain revealed a pentamer that lacks a cation-binding site.¹⁰⁶ Sequence analyses have identified 14 types (14E types) of NSP4 in RVA strains (Table 45.4). The highest sequence diversity of NSP4 is located in the cytoplasmic domain. It is unclear whether this sequence diversity is important and driven by interactions with specific residues on VP6 or divergent regions on VP4, or both. However, specific combinations of types of VP6 and NSP4 have been found in natural reassortants, suggesting these interactions are biologically important.³⁶⁵ There also may be host-specific interactions important for function, but these remain to be fully characterized.

Glycosylation of NSP4 is not required for its binding activity to DLP or for oligomerization, but it is required for interaction with calnexin.^{24,511,719} NSP4 also has a binding site for VP5' within VP4^{24,357} and may play a role in removing the transient envelope.⁷²⁵ Heterooligomers of NSP4, VP4, and VP7 have been detected in enveloped particles,^{465,602} and calcium has been shown to be important for oligomerization of these proteins in the ER⁶⁰³ as well as for proper folding of VP7 epitopes and outer capsid assembly.^{17,190,677} The precise mechanisms of how (a) the envelope on particles is removed, (b) the hetero-oligomeric complexes function in particle budding through the ER, and (c) the outer capsid is assembled onto the newly made DLPs remain poorly understood. However, siRNA experiments indicate that VP4 and VP7 are assembled onto the particle in the ER and VP7 is involved in removal of the transient envelope.^{163,453}

Rotavirus maturation is a calcium-dependent process, and virus yields are decreased when virus is produced in cells maintained in calcium-depleted medium.⁶⁷⁸ Viruses produced in the absence of calcium are almost exclusively DLPs, and budding of virus particles into the ER is not observed.⁶⁷⁷ The crystal structure of VP7 provides new understanding of the requirement of calcium in forming TLPs. VP7 forms calcium-dependent trimers (Fig. 45.4); two calcium ions coordinate between each VP7 monomer and stabilize the trimeric interactions. Electron cryomicroscopy and single-particle reconstruction of VP7-recoated DLPs show that the N-termini (residues 51 to 70) of VP7 interact with VP6 and the VP7 trimers clamp onto the VP6 trimer.¹²¹ Interestingly, unglycosylated VP7 made in the presence of tunicamycin is relatively stable in a calcium-free environment. The budding process can occur in the absence of calcium, but VP7 is retained within the ER.⁸ VP7 does not fold properly unless it is expressed with other rotavirus proteins, and calcium must be present in cells for correct epitope formation.^{190,191} Outer capsid assembly also requires proper formation of disulfide bonds on VP7.⁷⁰³ Earlier studies showed treatment of cells with various agents (tunicamycin, dithiothreitol, or calcium-blocking drugs, such as thapsigargin) results in a build-up of enveloped particles in the ER.^{341,503,589} These agents may disrupt the proper folding of VP7 that is required for removing the envelope.

NSP4 is a novel calcium agonist; it mobilizes intracellular calcium when expressed intracellularly by a phospholipase

C (PLC)-independent mechanism or by a PLC-dependent mechanism when it is added to cells from the outside.⁵¹⁸ Mobilization of intracellular calcium by a PLC-independent mechanism occurs through NSP4 functioning as a viroporin³⁵⁶ that is important for viral replication and assembly. Binding of VP6 on DLPs to NSP4 that occurs when viroplasm are capped by NSP4 is thought to trigger the budding process. Recent reports indicate that siRNA silencing of NSP4 expression in rotavirus-infected cells affects the distribution of other viral proteins, mRNA synthesis, and the formation of viroplasms where viral RNA replicates, suggesting global regulatory functions of NSP4 in rotavirus replication^{453,684} with molecular mechanisms that remain to be understood.

At least three pools of intracellular NSP4 exist in rotavirus-infected cells dependent on the level of NSP4 protein expression.⁴⁴ The first pool is represented by NSP4 localized in the ER membrane and is present throughout the course of infection. This pool serves as a receptor for the budding of immature viral particles into the ER, as described earlier, at the peak of viral infection, when all viral proteins are abundant (after 6 hours after infection). A second minor pool of NSP4 molecules enters the ER-Golgi intermediate compartment (ERGIC) and can be recycled back to the ER or may be a part of the nonclassical secretion pathway for delivery and cleavage of an NSP4 peptide into the medium of infected cells at early time points after infection⁸²⁶ when the levels of viral proteins are relatively low. The third pool of NSP4 molecules, distributed in cytoplasmic vesicular structures associated with the autophagosomal marker LC3 and viroplasms, is regulated by calcium levels and appears at 6 hours after infection, when there is an increase of intracellular calcium levels because of increased expression of viral proteins.⁵⁰⁴ NSP4 also interacts with calveolin-1, and this may be involved in the secretion of NSP4.^{566,826} Inhibition of NSP4 expression interferes with the formation of large viroplasms and affects viral protein expression⁴⁵⁵ and secondary viral mRNA synthesis in rotavirus-infected cells.⁶⁸⁴ The NSP4- and autophagic marker LC3-positive vesicles may serve as a lipid membrane scaffold for the formation of large viroplasms by recruiting early viroplasms or viroplasm-like structures formed by NSP2 and NSP5.²²⁶ These NSP4-positive membranes may also function to regulate packaging of the rotavirus genome and transcription through NSP4 association with VP6 on DLPs. The calcium-dependent compartmentalization of NSP4 into an autophagosomal pathway raises questions regarding the involvement of autophagosomal membranes in rotavirus replication and release of infectious virus from cells.

Understanding viral morphogenesis has been facilitated by the expression of the rotavirus structural proteins individually or in combinations in insect cells using recombinant baculoviruses.^{157,431,623,823} This approach first showed that the single-layered VP2 particle shell self-assembles when VP2 is expressed alone, and that all of the other capsid proteins can self-assemble into virus-like particles when co-expressed in the proper combinations. Virus-like particles composed of VP2, VP1/2, VP1/2/3, VP2/3, VP2/6, VP2/6/7, VP2/4/6/7, and VP1/2/3/6 can be made.^{157,823,824} The outer and inner capsid proteins of different virus strains can also reassort and are able to be transcapsidated onto other virus strains^{117,118} and infectious virus is produced.⁷³¹ These results demonstrate that the structural proteins contain the intrinsic information required to form particles and that co-expression of mutant

proteins is a feasible approach to analyze the domains responsible for the structural interactions between the proteins composing the virus particles. These particles have been useful to (a) analyze the role of cleavage sites in the spike protein in infectivity,²⁷² (b) investigate the role of individual structural proteins in inducing protective immunity,^{130,156,371,543,544} (c) probe the inner structure of particles by analyzing difference maps of particles with distinct protein compositions or by x-ray analysis,^{211,604,675} and (d) analyze RNA transcription and replication^{110,114,434,435} and RNA packaging and assembly. Future studies should address questions of which mechanisms control packaging of the viral genome and virus assembly.

Virus Release

Electron microscopy studies have shown that the infectious cycle ends when progeny virus is released by host cell lysis in nonpolarized cells.^{12,111,497} Extensive cytolysis late during infection and drastic alterations in the permeability of the plasma membrane of infected cells result in the release of cellular and viral proteins.⁵²⁷ Despite cell lysis, most DLPs and many TLPs remain associated with the cellular debris, suggesting that these particles interact with structures within cells. Interactions with cell membranes and the cell cytoskeleton have been suggested,⁵²⁷ and virus purification procedures generally use Freon extraction to release particles from cellular debris. Whether the cytoskeleton provides a means of transport of viral proteins and particles to discrete sites in the cell for assembly or acts as a stabilizing element at the assembly site and in the newly budded virions or whether particles are simply trapped by the cytoskeleton remains to be determined. VP4 interacts with actin and lipid rafts and can remodel microfilaments, and this has been suggested as a mechanism by which the brush border membrane of polarized epithelial cells is destabilized to facilitate rotavirus exit from cells.²⁶⁴

Rotavirus Effects on the Host Cell

Inhibition of Translation of Cellular mRNAs by NSP3

Viral mRNAs are capped but not polyadenylated, and viral proteins are translated by the cellular translation machinery. Most of the rotavirus structural proteins and the nonstructural proteins are synthesized on free ribosomes, although nascent proteins on free ribosomes have not been analyzed. Instead, this conclusion has been drawn based on the absence of signal sequences that would indicate targeting to the ER and lack of protection from digestion in *in vitro* protease protection studies.^{210,383} The viral glycoproteins VP7 and NSP4 are synthesized on ribosomes associated with the membrane of the ER and are co-translationally inserted into the ER membrane as a result of signal sequences at their N-termini. VP7 has a signal sequence that is co-translationally cleaved, whereas the signal sequence on NSP4 is not cleaved.

Translation of the viral mRNAs that are capped but not polyadenylated is facilitated by the action of the nonstructural protein NSP3, which is one of the five nonstructural proteins (NSP1, 2, 3, 5, and 6) that bind nucleic acid.^{671,713} NSP3 function parallels that of the cellular poly(A)-binding protein (PABP). The N-terminus of NSP3 interacts with the 3' consensus sequence (UGACC) of viral mRNAs and the C-terminus of NSP3 interacts with eIF4G as does PABP, but with higher affinity.^{311,596,597,600,748} These events lead to NSP3

evicting PABP from eIF4G, to the enhancement of translation of rotavirus mRNAs, and to the concomitant impairment of translation of cellular mRNAs.^{558,748} PABP evicted from eIF4G accumulates in the nucleus of rotavirus-infected cells, and this relocalization of PABP from the cytoplasm to the nucleus occurs relatively early in the infection cycle (~3 hpi) and requires a limited amount of NSP3.^{328,516} The complete depletion of PABP from the cell cytoplasm can reinforce the shutoff of translation of cellular polyadenylated mRNAs and may also enhance translation of viral mRNAs by making available other cellular factors involved in translation termination, RNA stability, or subcellular localization of host mRNAs that would normally be bound to cytoplasmic PABP.³²⁸

In vivo, NSP3 stimulates the translation of mRNAs in synergy with the cap structure, possibly enabling circularization of viral mRNAs and its delivery to ribosomes for viral protein synthesis^{126,748} (Fig. 45.12). Atomic structures of both domains of NSP3 complexed with bound ligands indicate that both domains have novel folds and NSP3 functions as a dimer (Fig. 45.13).^{182,311} Whereas the RNA-binding domain forms a rod-shaped symmetric dimer, the N-terminal domain tightly binds to the consensus 3' end of the mRNAs inside a tunnel formed at the dimeric interface. NSP3 and eIF4G also interact with a novel cellular protein, named *RoXaN*, which has a role in translation regulation that remains to be completely understood.⁷⁶⁵ However, the nuclear localization of PABP seen in rotavirus-infected cells is dependent on the capacity of NSP3 to interact with eIF4G and also requires the interaction of NSP3 with a specific region in *RoXaN*. This domain functions as a nuclear export signal and *RoXaN* tethers PABP with RNA. Thus, *RoXaN* is a cellular partner of NSP3 involved in the nucleocytoplasmic localization of PABP.³²⁸ The cellular chaperone heat shock protein 90 also binds to NSP3, prevents proteosomal degradation of NSP3, and increases dimerization of NSP3 required for its functioning to bind eIF4G and effect translocation of PABP to the nucleus.¹⁹⁹ This chaperone is induced by virus infection though activation of phosphoinositide 3-kinase (PI3K)/Akt and nuclear factor- κ B (NF- κ B) signaling that positively regulate rotavirus infection.^{198,199}

The binding of NSP3 to viral mRNAs has also been proposed as a possible mechanism to transport newly made mRNAs to viroplasms for subsequent replication. The cytoskeleton-binding function of NSP3^{288,487} might be involved in this process directly or NSP3 may interact with other host proteins that link the translational machinery and the cytoskeleton.

While NSP3 indeed inhibits translation of cellular mRNAs, a second mechanism of rotavirus-induced inhibition of cellular mRNA translation involves eIF2 α that is phosphorylated early after infection and is maintained throughout the virus replication cycle.^{515,516} This phosphorylation depends on the synthesis of VP2, NSP2, and NSP5, and the continuous phosphorylated status of eIF2 α is beneficial for the virus because viral mRNAs are preferentially translated efficiently while translation of most cellular proteins is stopped. Protein kinase R (PKR) is apparently responsible for this phosphorylation event that is triggered by viral double-stranded RNA detected in the cell cytoplasm outside viroplasms, which is a paradigm-shifting result as traditionally it has been assumed that rotaviral dsRNA is hidden from the interferon system by ensuring that genome replication takes place within replicative intermediate particles, such that single-stranded RNA is replicated as it enters these

FIGURE 45.13. X-ray structures of NSP3 and NSP4. **A:** Structure of the NSP3 N-terminal domain homodimer in complex with the 3' consensus sequence of rotavirus messenger RNA (mRNA).¹⁸² The dimeric subunits are shown in blue and yellow. A single 5' RNA segment (shown in ball and stick representation and indicated by an arrow) is buried within a basic deep tunnel formed in the asymmetric homodimer (shown in blue and golden yellow). Each subunit participates in different interactions with the mRNA segments. **B:** Structure of NSP3 C-terminal domain homodimer (shown in blue and golden yellow) in complex with the dimer of the short peptide of eIF4G (shown in green and red).³¹¹ **C:** Ribbon representation of the homotetramer (**left**) with each dimer shown in blue and green and the homopentamer (**right**) of NSP4 95-137. The red circle indicates the location of a divalent metal binding site, possibly binding calcium in the tetramer.^{72,106}

particles.⁵⁷² While further work is needed to characterize the nature of the viral dsRNA present in the cytoplasm of infected cells, the multiple mechanisms used by rotaviruses to remodel the host translation machinery in novel ways to ensure efficient translation of viral proteins will likely continue to reveal unique regulatory systems.⁶³⁶

Rotavirus Effects on Cellular Signaling Pathways and Apoptosis

The effects of rotavirus replication on cultured cells are cell-type specific. In nonpolarized tissue-cultured cells, rotaviruses are normally cytocidal viruses that rapidly kill the permissive cells they infect. Adaptation of rotaviruses to culture can be difficult and may require initial passage of virus in primary monkey kidney cells before adaptation to growth in continuous monkey kidney cell lines. Fully permissive cells generally exhibit cytopathic effect, and cell death is preceded by the shut-off of host RNA, DNA, and protein synthesis.^{99,209,489} Cell death seems to result from the function of a viral gene on a specific target rather than from cumulative effects on host metabolism, because certain ts mutants (ts groups F [VP2], G [VP6], H, and I [unassigned NSP3 and NSP4] [Table 45.4]) do not efficiently shut off host cell protein synthesis.^{216,619} NSP4 is a viroporin and a novel calcium agonist that mediates cell death by causing intracellular calcium levels to increase as well as by affecting the plasma membrane permeability and tight junctions of cells.^{504,540,704,726} Rotavirus induces the unfolded protein response of the cell but also controls it through NSP3 that reduces host protein synthesis.^{597,738} Rotavirus has been

reported to induce apoptosis in polarized epithelial cell lines as well as in mice infected with a murine strain of virus.^{69,107,702} Replication-competent virus is required to induce apoptosis, indicating that viral gene expression is a prerequisite and, when examined, intracellular calcium levels play a role, suggesting an effect of NSP4.¹⁰⁷

After infection of nonpolarized cells, rotavirus induces early alterations in vimentin,⁷⁸² in the cytoskeleton organization,⁷⁸³ and in the biochemistry of the host cell⁵⁹⁷ (Fig. 45.14). A dramatic decrease in the level of host cell proteins and a high level of viral proteins is observed.²⁰⁹ Rotavirus NSP1 has been shown to interact with IRF3, which results in its degradation; this is a mechanism by which rotavirus interferes with the innate host response of producing type 1 interferons^{38,294} (see Immunity section). Four proteins that are specifically up-regulated in rotavirus-infected cells have been identified, two of which correspond to the ER chaperones BiP and endoplasmic reticulum chaperone; however, the role of these proteins in the replication and morphogenesis of rotavirus particles remains to be established.⁷⁹⁹ In general, little is known about the involvement of host proteins in the diverse steps of the rotavirus replication cycle, except for in translation.⁷⁶⁵ A cascade of signals that the virus elicits in the host cell, the induced cytoskeletal changes, and the temporal program of cell gene expression after virus infection is being dissected with the application of microarray analysis to infected cells *in vivo* or in cultured cells.^{101,164,437}

Rotavirus infection in polarized human intestinal epithelial (Caco-2) cells leads to the alteration of many cell functions. Expression of enterocyte-specific genes is down-regulated at

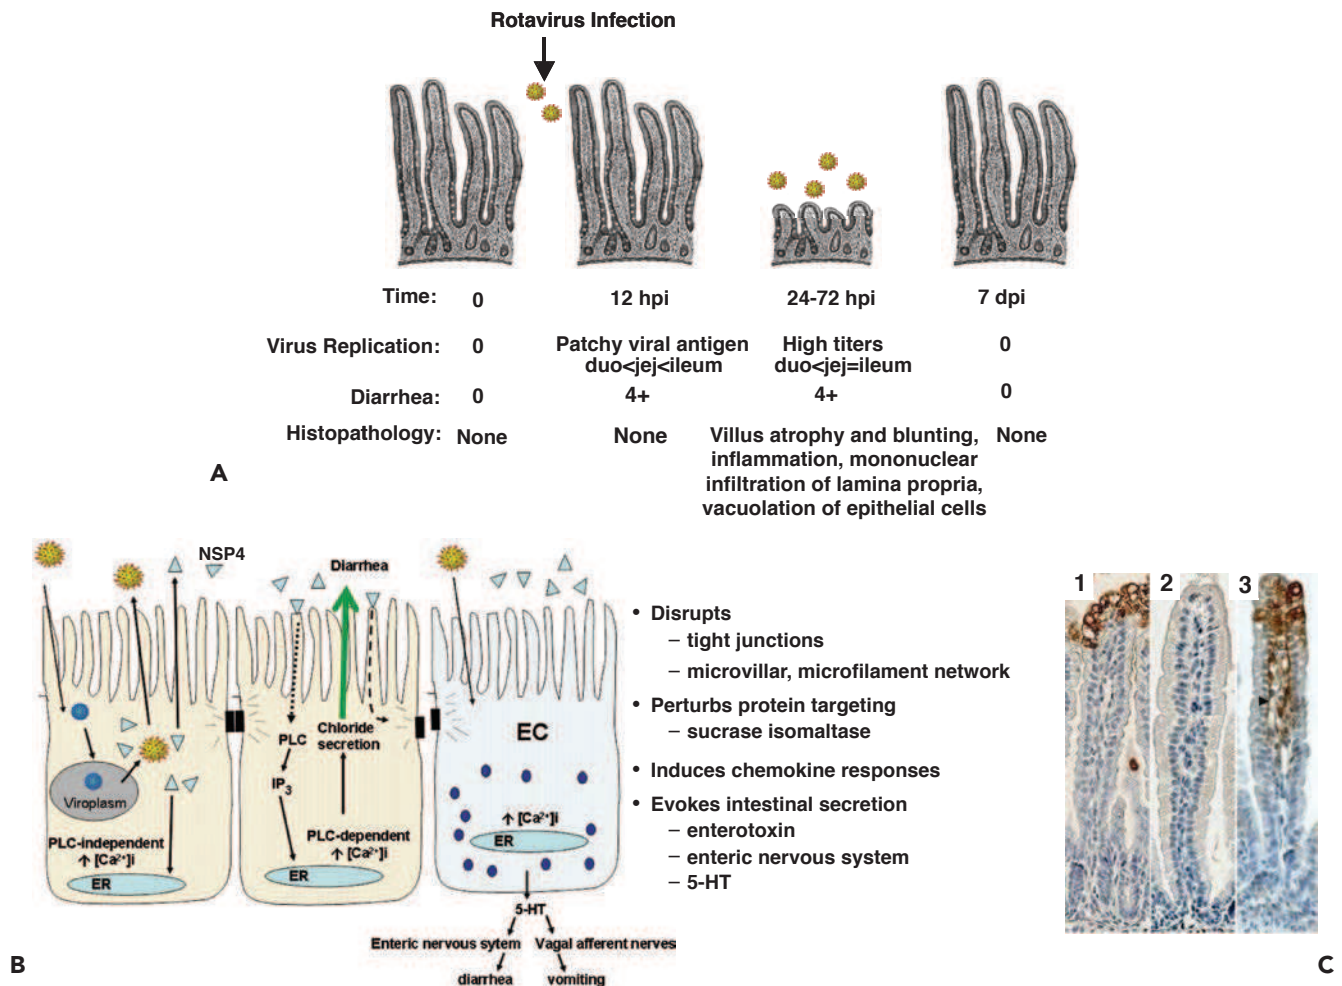

FIGURE 45.14. Rotavirus pathogenesis. **A:** Schematic of the histopathologic and clinical effects of rotavirus infection of intestinal cells. Rotavirus-induced diarrheal disease begins early after infection prior to significant histopathology of the infected mature enterocytes of the intestine. Diagram based on studies in piglets infected with virulent porcine rotavirus.⁷⁷⁰ It is thought that the early, profuse, secretory diarrhea is caused by the action of the rotavirus enterotoxin, NSP4 (see text and²²⁴). Histologic changes are seen at later time points when virus titers are high and loss of the differentiated enterocytes leads to malabsorption. The degree of villus atrophy can vary from species to species. The acute infection and disease normally resolves within 7 days in immunocompetent hosts. **B:** Model of rotavirus-induced diarrhea. Rotavirus infection of a polarized epithelial cell triggers many effects that contribute to pathogenesis. Infection of an initial cell (**left side**) results in virus entry and replication, formation of viroplasm, and release of virus and viral proteins. Intracellular NSP4 mobilizes intracellular calcium from internal stores, primarily the endoplasmic reticulum (ER), by a phospholipase C (PLC)-independent mechanism that involves NSP4 acting as a viroporin.³⁵⁶ An NSP4 or NSP4-derived polypeptide (amino acids 112 to 175) (triangles) are secreted from cells by a nonclassical secretory pathway. Enterocyte function is altered with many cellular messenger RNAs (mRNAs) being shut down and protein targeting is disrupted.^{69,617} Released NSP4-derived polypeptide affects uninfected cells, resulting in mobilization of intracellular calcium by a PLC-dependent pathway that activates or regulates chloride secretion. Tight junctions can also be disrupted by rotavirus infection as well as by NSP4 addition to uninfected cells. Finally, the enteric nervous system can be activated by mediators such as serotonin released from enterochromaffin (EC) cells infected with rotavirus or stimulated by NSP4.^{325,464} Disruption of epithelial cell structure and function occurs slowly (at 18 to 24 hours postinfection) and may lead to cell death and alterations of the paracellular pathway of fluid movement.^{86,131,379,381,504,550,704} Rotavirus infection of epithelial cells activates epithelial cell signaling that triggers crosstalk among the diverse types of cells that make up the villus architecture. This results in activation of the enteric nervous system, intestinal secretion, and immune responses.^{224,325,463,639} **C:** Viral antigen detection in mouse jejunum. Virus structural proteins are detected in enterocytes at the tips of intestinal villi at 4 days postinfection during murine rotavirus infection of neonatal mice (C1), while at the same time NSP4 is detected in epithelial cells at the tips of the villi, at the epithelial basement membrane, and in noninfected cells further down the villus (arrow in C3). NSP4 protein is not detected in uninfected mice (C2).⁷⁰

mRNA and protein levels,⁶⁹ and microvillar F-actin disassembly occurs,³⁷⁹ possibly due to the remodeling of actin by VP4 or NSP4.^{86,264} In addition, rotavirus infection causes alterations in tight junctions independent of virus-induced cytoskeletal rearrangements.^{188,550} Madin-Darby canine kidney (MDCK) cells support only restricted replication of rotavirus, but in both Caco-2 and MDCK cells, infected cells show transmembrane leaks or opening of tight junctions before the development of cytopathic effect and extensive virus release. Attachment of virus to, and entry into, Caco-2 cells does not cause any measurable transmembrane leak during the first hour of infection. Both VP8* and NSP4 have been shown to modulate tight junctions of polarized MDCK cells.^{537,704} It is possible that infected epithelial cells are sloughed from the intestine owing to the loss of tight junctions during the viral replication cycle and before development of cytopathic effect.

The epithelial cell response to rotavirus infection has also been examined in nonpolarized human intestinal cell lines, Caco-2 and HT-29 cells.^{102,682} Interleukin-8, growth-related peptide- α , RANTES (regulated on activation, normal T-cell expressed and secreted), and osteopontin are secreted from rotavirus-infected cells, and chemokine production is time and dose dependent. Interferons and granulocyte-macrophage colony-stimulating factor have also been detected in mice infected with rotavirus.⁶³⁹ The chemokine secretion response by enterocytes is an active component of the host response to rotavirus infection and may play a role in viral pathogenesis or in the immune response to rotavirus infection. Rotavirus infection of nonpolarized Caco-2 cells also increases mitochondrial superoxide dismutase expression and does not lead to induction of oxidative stress, possibly to prolong cell survival and allow for accumulation of viral particles before cell destruction and particle release.²⁶¹

Finally, rotavirus replication has been examined in polarized neuronal cells, where cytopathic effect again is not obvious. These infections are of interest because expression of VP7 is targeted to axons and dendrites by a pathway that does not involve the Golgi apparatus.⁷⁸¹ In contrast, NSP4 is localized solely in the cell body. Rotavirus infection stimulates alterations of specific neuronal proteins. Thus, the distribution of microtubule-associated protein 2, which is normally restricted to nerve cell bodies and dendrites, is altered and found in axons of cultured dorsal root ganglia and spinal cord neurons. This study indicates that selective interactions between certain viral and neuronal cytoskeletal proteins can occur and that noncytolytic viral infection can cause alteration in the polarized sorting of neuronal proteins.⁷⁸³ These studies are of interest because they highlight the usefulness of monitoring rotavirus protein transport to understand new intracellular trafficking and signaling pathways. It is not known if rotaviruses naturally infect neurons or if such infections result in activation of the enteric nervous system, which is a component of the pathogenesis of diarrheal disease.^{325,463}

Rotaviruses also have the ability to establish persistent infections in cell cultures^{28,123,219,520} and in mice with severe combined immunodeficiency disease (SCID).⁶³⁰ Analyses of these cells show that both viruses and cells co-evolve, and mutations in the virus confer trypsin-independent growth, suggesting that a protease requirement for efficient viral growth is a point of balance for viral growth and cellular survival during maintenance of persistent infection.⁵²⁰ Recognition that rota-

viruses cause persistent infections in SCID mice suggests that the *in vitro* observations of carrier cultures may have clinical relevance. The prolonged excretion and occasional extraintestinal spread of rotaviruses in children who are immunocompromised suggests that cell-mediated and innate immunity is important in limiting and clearing virus infections.^{273,353,580,792} Antibody, however, also plays a role in overcoming persistent infections in animals and children.^{91,315,317} The detailed mechanisms that regulate persistent virus–host relationships remain to be elucidated.

Genetics and Reverse Genetics

Genetic studies have been exploited to understand rotavirus gene structure and function. Temperature-sensitive mutant collections have been isolated from several rotaviruses, including the strains SA11, UK, and RRV.^{229,304,614–616} The most extensive ts mutant collection exists for rotavirus SA11, in which 10 of the expected 11 reassortment groups have been identified; 9 ts mutants have been assigned to genome segments (Table 45.5).¹⁶¹ Further biochemical and sequence analyses of these mutants or establishment of complementation systems with expressed gene products may permit dissection and localization of specific functional domains for the mutant genes.

Characterization of the genetic interactions between ts mutants has shown that recombination between pairs of ts mutants of SA11 occurs in the all-or-none fashion expected for recombination by a mechanism of reassortment of genome segments.⁶¹⁵ Genetic interactions of rotaviruses are influenced by factors similar to those that affect such interactions of other segmented viruses, including multiplicity of infection and the time of infection.⁶¹³ Maximal, or near-maximal, reassortment frequency is obtained at the earliest times when reassortment can be detected. This suggests that reassortment occurs early in the infectious cycle and that a single round of reshuffling of genes occurs, an observation consistent with the particle association of progeny dsRNA. Reassortment is efficient at nonpermissive temperatures and mutants from all reassortment groups can interfere with the growth of wild-type virus at both permissive and nonpermissive temperatures. These results are important to consider when trying to produce reassortants.

Naturally occurring rotavirus variants have also been found to be useful probes of gene function. Studies of a variant of the simian rotavirus SA11, which lacks glycosylated VP7, showed that glycosylation is not essential for virus infectivity or hemagglutination^{222,589} but that glycosylation can affect rotavirus antigenicity.¹⁰³ Another variant of SA11 with an altered genome segment 4 showed that the phenotype of certain reassortant constellations of genome segments depends on the parental strains used for analysis.¹¹³ This phenomenon has been confirmed with other reassortants containing specific combinations of VP4 and VP7, and this is beginning to explain some unexpected antigenic properties of some virus strains.^{114,197,414,422,528,800,831}

A reverse genetic system for rotavirus has been described in which a VP4 gene expressed from a complementary DNA (cDNA) was able to be rescued in a viable virus using conditions of strong selection.⁴¹⁸ This groundbreaking result proved that gene rescue is possible. Although the system remains inefficient, this breakthrough has allowed modifications of at least the VP4 gene to be studied. For example, a recombinant rotavirus with an antigenic mosaic of cross-reactive neutralization epitopes has

shown the feasibility of engineering novel vaccines.⁴¹⁷ In addition, the trypsin cleavage site of VP4 has been modified to a furin-sensitive site to determine if this would further enhance infectivity.⁴¹⁹ The mutant VP4 on virus was efficiently cleaved by furin, but the virus showed impaired infectivity, and infectious virus release into the extracellular medium was impaired, suggesting that intracellular cleavage of VP4 by furin is disadvantageous for RV infectivity, possibly due to an inefficient virus release process.⁴¹⁹ The efficiency of this system has been improved by using two independent strategies (use of a ts mutant and RNA interference [RNAi]-mediated degradation of the wild-type target mRNA) to drive the selection of recombinant viruses.⁷³³ A reverse genetics system for rotaviruses also has been achieved by another modified approach based on the preferential packaging of rearranged genomic RNA segments.⁷³⁶ In this case, an *in vitro* engineered form of a rearranged segment from a human rotavirus derived from cloned cDNA and transcribed in the cytoplasm of cells by using the T7RNA polymerase replaced the wild-type segment of a bovine helper virus. This system was used to enable the introduction of a mutated gene expressing a modified nonstructural protein into an engineered mono-reassortant infectious rotavirus without the need for any selective pressure other than selection inherent to cell culture. Continued improvements of these approaches and their use to study specific functions of the viral proteins and the biology of viral replication will be required to truly understand the molecular basis of viral pathogenesis.

PATHOGENESIS AND PATHOLOGY

Our understanding of rotavirus pathogenesis is based primarily on work with animal models. Such studies allow the use of characterized homologous (viruses initially isolated from the experimental host species) and heterologous (viruses initially isolated from a host species distinct from the experimental species) viruses. In animals, virus replication can be analyzed in different tissues to obtain precise information about the sites of virus replication and host response to infection. Rotaviruses replicate primarily, but not exclusively, in the nondividing, mature enterocytes near the tips of the small intestinal villi, suggesting that differentiated enterocytes express factors required for efficient infection and replication. Although the small intestine is clearly the site of optimal viral replication, several recent studies have demonstrated antigenemia, viremia, and limited systemic replication likely occurs in a variety of sites, although there is little evidence that this systemic spread and replication is responsible for any specific pathologic findings in normal hosts.^{63,64,230,239,533,611,618} Studies have demonstrated, however, that in severely immunocompromised infants, rotaviruses can replicate and cause abnormalities in the liver and other organs,²⁷³ and that in suckling mice without an intact interferon signaling system, some strains of rotavirus replicate very efficiently in the biliary tree and pancreas and cause biliary atresia and pancreatic disease.²³⁴ This strain-specific predilection to replicate in the biliary tree and pancreas of mice deficient in interferon signaling has been linked to specific phenotypic characteristics of VP4 and NSP1 and involves viral binding and interferon antagonism.²³⁷ The relationship between the ability of certain rotavirus strains to spread and replicate systemically and the association of rotavirus infection

or vaccination with several systemic manifestations such as fever or intussusception is presently unknown.

The severity, localization, and histological findings of intestinal infection vary among animal species,^{69,206,617} between strains in a single species, and between studies; however, in virtually all cases pathologic changes due to rotavirus infection are primarily limited to the small intestine.^{302,617} In animal models, infection is associated with a few visible lesions in the intestine, with some lesions such as enterocyte vacuolization and loss, or with significant histopathology changes such as villus blunting and crypt hyperplasia. Inflammation is mild compared with that observed with many other intestinal pathogens, especially bacterial pathogens. In many cases, no clear correlation exists between the degree of histopathology changes and the severity of diarrheal disease. Even in species where histopathology is significant, such as cows and pigs, frequently significant diarrhea occurs before the signs of intestinal pathology. This dichotomy has been explained by the existence of a variety of mechanisms that cause disease symptoms (primarily vomiting, diarrhea, and fever in humans) that are briefly reviewed here. Several of these mechanisms are not dependent on either tissue disruption or inflammation. More extensive reviews are available.^{32,90,145,218,303,463,617,649}

Pathogenesis of rotavirus infection is multifactorial, and both host and viral factors affect the outcome of disease. For example, the age of inoculation impacts severity of symptoms: in newborn or suckling interferon signaling-deficient mice, infection can result in biliary atresia; in 0- to 14-day-old mice and rats, diarrhea and some extraintestinal replication of virus occur; in adult mice, infection occurs in the absence of diarrhea. Genetic analysis of selected virus reassortants identified several viral proteins that are involved in virulence (VP3, VP4, NSP1, VP6, VP7, NSP2, NSP3, and NSP4).^{82,237,344,552,617} These proteins are thought to play roles in the efficiency of virus replication (VP3, NSP2, VP6, and NSP3), shut-off of host protein synthesis (NSP3), extraintestinal spread and replication of virus (NSP1 and NSP3), virus entry into cells (VP4 and VP7), regulation of the induction of interferon (NSP1), and the induction of diarrhea (NSP4).

A major confounder in interpreting the various genetic studies of rotavirus pathogenesis and virulence is the general failure by many investigators to carefully define what component of pathogenesis is being examined. For example, some studies have simply examined disease phenotype (diarrhea/no diarrhea), whereas others have attempted to quantify the level of diarrhea. Some studies have focused on the quantity of viral replication in the intestine or shedding in the feces as a surrogate of pathogenesis, and other studies have examined transmissibility between susceptible hosts. Finally, in some studies, disease due to extraintestinal replication was examined as a measure of virulence. Depending on which one of these various pathogenicity-associated phenotypes is under study, both the host-associated mechanisms and the viral genes involved are likely to vary.

As a more specific example, analysis of the most prominent aspect of rotavirus pathogenesis, rotavirus diarrhea-inducing capacity, has yielded discrepant results. Rotavirus diarrhea-inducing capacity has been attributed to several different mechanisms, including malabsorption secondary to destruction of enterocytes or disruption of enterocyte absorptive functions, villus ischemia, a virus-encoded enterotoxin (NSP4), and activation of the enteric nervous system.^{33,325,463,464,556} Each of these

distinct mechanisms would likely be affected by a reduction in viral replication capacity of any cause. In fact, several studies in people have linked the level of rotavirus shedding in the feces with the diarrheal severity,³⁸⁶ although recent studies in India of neonates symptomatically or asymptotically infected with a similar rotavirus strain failed to find a correlation between diarrheal severity and either the amount or the duration of viral shedding.⁶¹² Hence, it is important when studying the basis of rotavirus virulence to be cognizant of the constraints and limitations associated with the specific choice of experimental system or aspect of pathogenesis under examination.

In regard to pathogenesis, perhaps the most critical determining factor differentiating the virulence potential of one rotaviral strain from another is whether the virus examined is homologous or heterologous for the infected host. Homologous strains (strains generally isolated from the host species in question) tend to replicate efficiently, often causing diarrhea at a very low inoculation dose, and spread efficiently in that host. In general, heterologous strains (not routinely isolated from that host in question but found frequent in another host species) replicate poorly compared to the homologous strains, only cause diarrhea with large inoculation doses, and do not spread efficiently to other susceptibles. Host-range restriction barriers to rotavirus infection, while substantial, are not absolute, and there are numerous examples of zoonotic transmission to people.⁴⁷³ The mechanistic and genetic basis for host-range restrictions are one set of factors that often play a role in virulence. Host-range restriction also forms the mechanistic basis for the attenuation of several rotavirus vaccines and vaccine candidates. Viral determinants of host-range restriction have not been as thoroughly investigated as one might imagine, and studies have been basically limited to experimental infections of reassortant viruses in pigs and mice. In mice it appears that NSP1, a gene product involved in suppressing innate immune responses, and probably VP4, the viral attachment protein, are both important factors governing host-range restriction in the gut based on genetic studies⁸² (H. Greenberg, unpublished data). In pigs NSP1 may not be involved.^{207,410}

There are factors other than replication potential that likely affect virulence. The discovery of NSP4 as the first viral enterotoxin is of interest in this regard, because it shows this protein has pleiotropic properties in addition to its intracellular role in viral replication and morphogenesis (see earlier). NSP4 has been shown to induce age-dependent diarrhea in mice that mimics disease caused by rotavirus infection; this has been confirmed for the NSP4 proteins from several group A and non-group A viruses.^{303,342} How NSP4 might function as a virulence factor has been determined by analyzing reassortant viruses in gnotobiotic pigs,³⁴⁴ although other genetic studies have not directly linked NSP4 with diarrhea,⁸² and virulent and avirulent strains of rotavirus often have similar or identical NSP4 genes. Several features of a model for the function of NSP4 as an enterotoxin have been confirmed²¹⁴ (Fig. 45.14). The predictions that NSP4 would be released from rotavirus-infected cells and have paracrine effects on adjacent uninfected cells have been confirmed *in vitro* and *in vivo*. The mechanism of NSP4 enterotoxin function has been shown by extracellular administration of NSP4 to the intestinal mucosa and to crypt cells from mice and to human intestinal cell lines. The extracellular administration triggers a signal transduction pathway that leads to mobilization of intracellular calcium, $[Ca^{2+}]_i$,

through a PLC-dependent pathway and chloride secretion (Fig. 45.14). *In vivo*, in mice infected with a murine rotavirus strain, NSP4 is detected both in cells at the tips of the intestinal villi (together with other structural proteins) as well as by itself at the basolateral surface of cells and in cells in the lower part of intestinal villi (Fig. 45.14). The basolateral localization of NSP4 is consistent with the observation that NSP4 interacts with laminin β -3 and fibronectin.⁷⁰ Basolateral integrins $\alpha 1\beta 1$ and $\alpha 2\beta 1$ are receptors for the rotavirus enterotoxin.⁶⁷⁴ An antibody to NSP4 and siRNAs to NSP4 attenuate rotavirus-induced diarrhea in mice,^{119,127,346} but levels of antibody to NSP4 in children have not been directly correlated with protection, and thus the precise mechanism through which NSP4 induces diarrhea in people remains to be characterized. An assay to measure functional antibody may be needed.

A role for the enteric nervous system in rotavirus diarrhea has been shown by the ability to attenuate rotavirus-induced diarrhea in mice and children with drugs that block this pathway.^{423,463,656} NSP4 or other factors released from virus-infected cells may mediate this effect directly or by stimulating responses from enterochromaffin cells. These results suggest common mechanisms between diarrheas induced by viruses and bacteria not previously appreciated. Recent studies using human enterochromaffin cells (ECs) as well as *in vivo* analyses in the mouse model indicate that rotaviruses can infect ECs and that this infection induces secretion of serotonin. Serotonin release is also stimulated by NSP4 but not by inactivated virions. The release of serotonin, which acts through the enteric nervous system, could be responsible for the well-documented association of rotavirus infection with vomiting.³²⁵

EPIDEMIOLOGY

Morbidity and Mortality in Children

Until the discovery of the rotaviruses, only a small proportion of severe diarrheal illnesses of infants and young children could be linked to a specific etiologic agent.⁸¹⁴ As data from epidemiologic studies in developed and developing countries accumulated, it became clear that rotaviruses were the major etiologic agents of serious diarrheal illness in infants and young children throughout the world.⁵⁶ The impact of rotavirus infection on infant mortality was far greater, however, in the poorest regions of Asia and Africa (Fig. 45.2).

Although rotavirus diarrhea occurs with high frequency in developed countries, mortality is low. In the United States, rotaviruses cause about 5% to 10% of all diarrheal episodes in infants and children younger than 5 years of age, and prior to the advent of widespread vaccination (see Prevention and Control Section later), these viruses accounted for 30% to 50% of the severe diarrheal episodes.^{469,563,564} In this age group in the United States in the prevaccination era, rotaviruses were responsible annually for more than 3 million episodes of diarrheal illness, 500,000 visits to a medical practitioner, 60,000 to 70,000 hospitalizations (including those with nosocomial rotavirus discharge diagnoses), and 20 to 40 deaths.^{183,213,242,277} Similar epidemiologic studies from Europe demonstrated that before the institution of rotavirus vaccines, rotavirus infection was responsible for approximately 3.6 million episodes of diarrhea, over 87,000 hospitalizations, 231 deaths, between 28% and 52% of acute gastroenteritis cases, and up to two-thirds of

related hospitalizations and emergency room visits.^{692,742} There is not yet reliable data available on how the widespread use of rotavirus vaccines has affected total diarrheal illness numbers in the United States, but the number of severe illnesses and hospitalizations due to rotavirus has decreased by more than 85% for fully vaccinated children in the United States, and a recent study from Mexico indicates that vaccination resulted in a significant decrease in rotavirus-associated mortality.⁶⁹⁵

Prior to the implementation of widespread vaccination, practically every child younger than 5 years of age in the United States experienced a rotavirus infection of severity ranging from asymptomatic to life threatening; 1 in 100,000 children in this age group died from rotavirus infection.²⁴⁰ Directly calculated population-based rates for rotavirus hospitalizations and emergency department visits were 22.5 hospitalizations and 301.0 emergency department visits per 10,000 children younger than 3 years of age.⁵⁷⁸ In the United States, rotavirus diarrhea was estimated to result in more than \$400 million in direct medical costs (primarily for hospitalization) and more than \$1 billion in total societal costs (primarily for loss of work time of parents or caregivers) prior to the introduction of widespread vaccination.²⁴⁰ The high morbidity rate but low mortality rate was due to the development during the 1940s of effective means for replacement of fluid and electrolytes lost during acute illness and their routine use in developed countries.^{203,652} Widespread use of oral rehydration therapy was associated with a marked decrease in mortality from all forms of infantile diarrhea in the United States and other developed countries since the mid-1900s.

In developed countries, the widespread distribution of rotaviruses in the community is documented by the universal acquisition of serum antibodies to these viruses at an early age. Prior to rotavirus vaccine use, more than 90% of infants and young children in the Washington, DC area possessed rotavirus antibodies by the end of the third year of life, a pattern similar to that observed for respiratory syncytial and parainfluenza type 3 viruses.³⁹⁵ The high prevalence of rotavirus antibodies is maintained into adult life and periodically undergoes significant boosts, suggesting that subclinical rotavirus reinfection occurs relatively commonly throughout life. A similar pattern of rapid acquisition and maintenance of rotavirus antibody has also been observed in many other parts of the world. The widespread vaccination of children starting at 2 months of age in the United States means that acquisition of serum antibody can no longer be used as a surrogate for natural infection.

Cross-sectional studies of hospitalized infants and young children with diarrheal illnesses have yielded the most compelling evidence for the importance of rotaviruses as etiologic agents of severe diarrhea of early life. For example, during a period of over 8 years, 34.5% of 1,537 infants and young children admitted with diarrhea to a Washington, DC hospital shed rotavirus in their feces on admission.⁷⁴ In a similar study in Japan of over 6 years' duration, 45% of 1,910 pediatric patients with diarrhea were rotavirus positive.⁴²⁰ This pattern has been shown in other studies over shorter time periods.⁷⁵⁸ A 13-year, cross-sectional study of hospitalized children with gastroenteritis reported from Australia found that 39.6% of 3,785 children shed rotavirus in feces on admission.³⁴ Notably, 55% of children (12 to 23 months of age) with gastroenteritis were rotavirus positive. Rotavirus gastroenteritis was also often observed in the younger than 6 months of age group (18.7%

of cases) as well as the group consisting of 5- to 13-year-olds (16% of cases).

In developing countries, rotaviruses are consistently the leading cause of life-threatening diarrhea.^{78,562} The global burden of rotavirus diarrheal disease in infants and children younger than 5 years of age worldwide is estimated to be more than 100 million episodes, over 20 million outpatient visits, and a staggering more than 500,000 deaths (range 475,000 to 580,000)^{562,563} (Fig. 45.2). Hospital-based studies in Asia, Africa, and Latin America indicate that 25% to 55% of hospitalizations for diarrheal illnesses in children younger than 5 years of age are linked to rotavirus infection,²⁷⁷ with more than 80% of all rotavirus deaths occurring in low-income countries of South Asia and Sub-Saharan Africa.^{78,562,563} For example, recent estimates indicate that India, China, and Pakistan have approximately 122,000, 27,000, and 20,000 rotavirus-associated deaths, respectively, whereas the African countries of Nigeria, Democratic Republic of the Congo, and Ethiopia have approximately 50,000, 30,000, and 27,000 deaths per year, respectively.^{78,562} Thus, during the first 5 years of life in both developed and developing countries, in the absence of vaccination, every child will experience an episode of rotavirus infection and many will have an associated diarrheal illness, but the consequences of the rotavirus infection are likely to be quite different depending on where the child lives.

Although rotavirus vaccines have been widely deployed in a number of middle-income countries in Central and South America, vaccines have not yet been broadly available in the poorest countries of Asia and Africa. Widespread vaccination would dramatically lower the worldwide mortality and economic burden of rotavirus infection if the difficulties in financing and delivering the rotavirus vaccine could be overcome.⁵²²

Rotavirus Serotypes

The serotype classification of various rotavirus strains and the structural and genetic basis for this classification scheme is covered in the earlier Classification section of this chapter. Basically both surface proteins, VP4 (P types) and VP7 (G types), are targets of neutralizing antibodies and serotypic classification is based on a binary system including both proteins. There are currently 27 distinct G serotypes and 35 P serotypes found among group A rotaviruses of humans and animals.⁴⁸² Fortunately, the number of G and P combinations commonly found in people is substantially lower than the number of possible combinations, although approximately 12 G types (1 to 6, 8 to 12, and 20) and 15 P types (1 to 6, 8 to 11, 13, 14, 19, 25, and 28) have been isolated at one time or another from people.^{482,660} The development of the monoclonal antibody-based ELISA for identification of the VP7 type of clinical isolates and the subsequent application of RT-PCR genotyping and nucleotide sequencing have expanded our understanding of the epidemiology of rotavirus serotypes with regard to infection, disease, and immunity.^{241,267,660}

The global distribution of common human rotavirus serotypes has been consistent from 1989 to the present with the VP7 "G" serotypes 1, 2, 3, and 4 continuing to make up the great majority of strains detected, especially in the developed world. In the last decade, G9 strains have emerged as important serotypes in some parts of the world, such as Australia, the United States, Ghana, India, and Brazil^{2,21,267,413,660}; G8 strains have emerged occasionally in parts of Africa.^{267,660,728} A comprehensive

review encompassing 124 studies published between 1989 and 2004 of the global distribution of rotavirus serotypes and genotypes in 52 countries on five continents, which included 45,571 typed strains, showed that G1 strains were the most frequently detected serotype in each of the continents. G1, G2, G3, and G4 strains accounted for 97.5% of all rotavirus infections studied in Asia, North America, and Europe and 83.5% to 90.4% in South America, Africa, and Australia. G5, G8, G12, and G9 strains appeared focally in several areas, with G9 strains occasionally being predominant.⁶⁶⁰ More recent reviews emphasize the persistent frequency of G1 to G4 strains over the past decade and the emergence of G9 and G12 strains in a variety of locations around the world.^{484,547,658}

Serotype analysis of clinical isolates for their VP4 serologic specificity has not been widely performed because of the paucity of appropriate, monospecific serologic reagents. RT-PCR for VP4 genotyping has made it possible, however, to characterize rotavirus-positive specimens from epidemiologic surveys.^{267,660} Based on sequence analysis, VP4-type P1A[8] strains are the most frequently observed strains in humans followed in frequency by P1B[4] strains. This is to be expected because the P1A[8] genotype is almost always found in association with G1, G3, G4, and G9 rotavirus strains. The other major G serotype, G2, characteristically has VP4 P1B[4] specificity. Although various combinations of G and P serotypes or genotypes have been described, a review of 16,474 strains evaluated for both VP7 and VP4 specificities in 124 studies indicated that four predominant P-G combinations, P[8]G1, P[4]G2, P[8]G3, and P[8]G4, composed 88.5% of all the strains.⁶⁶⁰ A more recent analysis indicates that P[8]G9 strains are also frequently isolated in humans.²

The reason serotypic classification studies have received so much attention is because it is assumed that such classifications will be relevant to and correlate with the induction of protective immunity. With the recent demonstration that a G and P monotypic vaccine (see Prevention and Control section later) appears to efficiently protect against all rotavirus-associated illness in humans, the intense focus on human rotavirus serotypes must be called into question. Additional time will be required to determine the precise and long-term relationship between human rotavirus serotypes and protective immunity, but initial indications are that heterotypic immunity plays a larger role in the epidemiology of disease during rotavirus infection than in some other viral infections, and that despite the very large potential serotypic diversity of rotaviruses, immunity is generally generated rapidly after a limited exposure to a restricted number of serotypes, at least in developed countries.

Rotavirus Infections in Adults

Adults are frequently reinfected with rotavirus, but characteristically with only minimal to moderate or no clinical manifestations. For example, 22 of 40 adult household contacts of children hospitalized with rotavirus gastroenteritis had serologic evidence of rotavirus reinfection at the time of their child's admission to the hospital, although the adults were asymptomatic.⁴¹¹ When symptomatic, infection in adults is similar to that seen in infants, although diarrhea, vomiting, and dehydration are not usually severe.¹⁴ Although subclinical rotavirus infection is the most common outcome in adults, rotavirus gastroenteritis in adults has been described in army recruits in Finland as well as in patients (some geriatric) and staff in hospitals in

various countries.³⁴⁷ In a recent study from China, rotavirus was second to noroviruses as a cause of viral gastroenteritis in adults.⁴⁴⁷ Outbreaks in adults have been described, but these are considered to be unusual, isolated events.^{251,444} Rotavirus infections have also been associated with traveler's diarrhea in certain settings, and a recent large review of the global etiologies of traveler's diarrhea found that rotavirus infection was responsible for approximately 4% to 7% of cases depending on the location.⁶⁷⁶ Symptomatic rotavirus gastroenteritis can also be seen in adults undergoing bone marrow and other transplantations^{5,833} as well as in some patients with malignant disease undergoing chemotherapy.⁴⁴¹

Group B rotaviruses (adult diarrheal rotaviruses [ADRVs]) have been implicated in several large outbreaks (involving up to 20,000 individuals) of severe gastroenteritis in adults in various parts of China as well as smaller outbreaks and endemic disease in Bangladesh and India.^{354,407} Affected individuals often had cholera-like, severe, watery diarrhea, and a few elderly patients died. To date, group B rotavirus infections appear to occur primarily as isolated epidemics or sporadic cases, possibly due to contamination of water sources.

Nosocomial Infections

Nosocomial rotavirus infections occur frequently. For example, 10 (17%) of 60 children hospitalized for nondiarrheal disease during a period of rotavirus prevalence developed a diarrheal illness associated with a rotavirus infection.⁶⁵¹ In another study, approximately one of every five rotavirus infections appeared to be hospital acquired.⁵⁰⁶ The important contribution of nosocomial infections to the composition of hospital discharge diagnoses attributed to rotaviruses has been documented in various studies: a median of 27% of patients in developed countries and 32% in developing countries discharged with a diagnosis of rotavirus diarrhea were likely to have acquired the rotavirus infection while in the hospital.²⁴⁰ A review of nosocomial infections in European countries showed that infections are mainly associated with young infants (0 to 5 months of age) as opposed to older age groups in the community and that a sizeable proportion of the infections are asymptomatic.²⁸² The introduction of rotavirus vaccines leads to a significant reduction in hospital-acquired as well as community-acquired rotavirus infections.¹³ Nosocomial infections have also been described in various neonatal nurseries around the world.^{55,168,443} These infections are usually subclinical, although nosocomial outbreaks of rotavirus gastroenteritis have been described in a newborn nursery in Italy²⁷⁰ and in various neonatal intensive care units in the United States.²⁴⁰

Transmission

Rotaviruses are very contagious,²⁹⁵ with as little as one tissue culture infectious dose able to cause illness in a fully susceptible host. Further enhancing transmission potential, the virus is very stable in the environment and is shed in very large amounts in the feces.²²³ Rotaviruses are generally transmitted by the fecal-oral route. Oral administration of rotavirus-positive stool material induces diarrheal illness and viral shedding in adult volunteers.^{402,775} There has been speculation that rotaviruses are also transmitted by the respiratory route.³²² Evidence for this is circumstantial and rests on the following observations: (a) the rapid acquisition of rotavirus antibodies in the first few years of life in all settings, regardless of hygienic standards; (b) a few

large outbreaks in which a fecal–oral spread could not be documented²⁵¹; and (c) the occurrence of respiratory symptoms in a proportion of patients with rotavirus gastroenteritis.³²² Scattered reports have appeared of rotavirus detection in the upper respiratory tract; however, the predominance of data suggests that the respiratory route is not the usual mode of transmission.^{766,830} The source of rotavirus infection for the young infant who is normally not in contact with other infants and young children with gastroenteritis is not well understood. Most likely, infection is acquired from an older sibling or parent with subclinical infection.^{208,308} Shedding of rotavirus from the intestinal tract before onset of diarrhea or following cessation of diarrhea has been well documented.⁵⁹⁵ The duration of rotavirus shedding in 37 hospitalized children ranged from 4 to 29 days, with a median of 7 days, as measured by ELISA, whereas by the more sensitive PCR assay shedding was detected for up to 57 days, with a median of 10 days.⁶²⁷ Shedding in severely immunocompromised children can be even more prolonged.²⁷³

Resistance to physical inactivation may also contribute to the efficient transmission of the human rotaviruses. This inference is drawn from the observed stability of various human and animal rotaviruses at ambient temperatures and from the low doses required for infection of humans and animals.^{223,409,775} For example, porcine rotavirus present in feces retained infectivity for over 2 years when refrigerated.⁶²⁰ Other observations that suggest that environmental contaminations are viable sources of infection include (a) the persistence of rotavirus infection in certain newborn nurseries and (b) the high frequency of nosocomial rotavirus infection in hospitals (see earlier). The ability of rotaviruses to survive on various surfaces under different conditions may contribute to its rapid spread.⁷⁹⁰ Although rotaviruses have been detected in both raw and treated sewage, it is unlikely that contaminated water (which is important in group B rotavirus outbreaks) plays an important role in transmission of group A rotaviruses.^{354,688} However, an apparent community-wide water-borne epidemic of group A rotavirus was documented in Turkey in 2011.⁴²⁴ Effective disinfection of contaminated material and careful hand washing constitute important measures to contain rotavirus infection, especially in hospitals and institutional settings.^{61,657,705,790} Rotavirus has been detected on moist surfaces in daycare centers and, in one controlled study, rotavirus transmission to volunteers was prevented if a surface first contaminated with rotavirus was sprayed with a disinfectant (Lysol) prior to contact with the volunteer.^{94,773}

There has been speculation on the role of animals as a source of rotavirus infection of humans. This idea gained support with the observation that certain animal rotaviruses share a neutralization antigen with human rotaviruses and that certain naturally occurring animal rotavirus strains may infect humans or form reassortants with human rotaviruses.^{485,530} Nonetheless, interspecies transmission and persistence of animal strains in the human population appears to be rare. It should be noted, however, that human-bovine reassortant strains (I321, 116E) and a human–porcine reassortant strain (G5) have been endemic in selected areas in India and Brazil, respectively.^{11,169,276} Human–simian rotavirus reassortants have also been detected in India.²⁵ Recent large-scale full genomic sequencing of rotavirus isolates from around the world indicates that genome segments of animal rotavirus origin are present in human isolates at higher frequency than had been expected.⁴⁷³ However, to date, such studies have focused on sequencing of isolates that were unusual

from a serologic or electrophoretic perspective, so the actual frequency of such human/animal reassortment in the field is not clear. In a large unpublished sequencing study of rotavirus isolates collected over several seasons from the United States, the rate of human/animal reassortants was very low (John Patton, personal communication).

Incubation Period

The incubation period of rotavirus diarrheal illness has been estimated to be less than 48 hours.¹⁷¹ The onset of experimentally induced rotavirus diarrhea in adult volunteers occurred 2 to 4 days after challenge.^{401,402} One of the volunteers who developed diarrhea 3 days after virus administration developed a fever and vomited on the first day after challenge, thus indicating from such studies that the incubation period of the illness under experimental conditions was 1 to 4 days.

Distribution

Geographic Distribution and Seasonal Patterns

Rotaviruses have been detected throughout the world wherever they have been sought.^{78,279,563,610,767} These viruses consistently constitute the major etiologic agents of severe infantile diarrhea in every country where this disease has been studied. Prior to the widespread introduction of rotavirus vaccines, rotaviruses displayed a marked seasonal pattern of infection in developed countries, with epidemic peaks occurring in the cooler months of each year.⁵⁶⁰ This recurring pattern has been observed in the United States, Europe, Australia, and Japan.^{34,74,166,420} The cause for this striking seasonal pattern is not known, but the influence of low relative humidity in the home has been suggested in some but not all studies as a factor facilitating the survival of rotaviruses on surfaces.^{73,420,512}

An analysis of hospitalizations for diarrhea in the post-neonatal period and the temporal distribution of rotavirus isolations from various centers suggested that rotavirus diarrhea spreads from the west to the east in the United States, appearing in the fall in the southwest and spreading progressively across the country, so that by late winter and spring it has reached the northeast and maritime Canada.⁴³⁶ Of note, following the introduction of rotavirus vaccination, the marked seasonality of rotavirus infection declined substantially, and the initiation of the annual epidemic occurs later in the season.^{166,717} The usual seasonal pattern of rotavirus infection observed in the temperate climates does not occur uniformly in other areas of the world; many locations in the tropics show no, or a diminished, seasonal trend.^{336,438} Recent modeling studies have suggested that the relative lack of rotavirus seasonality observed in many tropical countries may be due to the high birth rates and transmission rates typical of developing countries.¹⁶⁶

Age, Sex, Race, and Socioeconomic Status

In developed countries, rotavirus gastroenteritis of sufficient severity to require hospitalization characteristically occurs most frequently in infants and young children from approximately 6 months to 2 years of age.⁵⁵ Infants younger than 6 months of age experience the next highest frequency of such illness. In certain studies, especially in less developed countries, the younger than 6 month group had the highest frequency of severe disease.^{160,208,699,740} In one study from the United States, the age distribution of patients admitted to the hospital with gastroenteritis of any cause was different for black and nonblack

patients; 59% of all black patients admitted for gastroenteritis were younger than 6 months of age, whereas most non-black patients were older.⁷⁶ This difference was also reflected in admissions for rotavirus diarrhea. Because the children were predominantly from inner-city areas, these differences may have reflected the effects of crowded living conditions, which may have allowed earlier and more efficient transmission of the virus.

In an Australian study of 4,637 children from 0 to 14 years of age hospitalized with gastroenteritis, the peak incidence of rotavirus gastroenteritis was in children 12 to 23 months of age. Rotavirus was also a frequent cause of gastroenteritis in children younger than 6 months of age (18.7%). There were also rotavirus-associated gastroenteric illnesses in children 5 to 13 years of age, and rotavirus was identified as the sole pathogen in 16% of patients in this age group. The low frequency of clinical illness in most (but not all) normal neonates who shed rotavirus remains unexplained.⁵⁶ It seems clear, however, that such asymptomatic neonatal infection is able to induce a protective immune response in the infected children.²⁷⁶ Malnutrition is considered to play an important role in increasing the severity of clinical manifestations of human rotavirus infections.^{85,167} This phenomenon has been reproduced in experimental mouse and piglet models.^{739,832} It has also been suggested that repeated diarrheal infections may be a precipitating factor in the development of malnutrition as these infections damage the intestinal mucosa so that absorptive cells are compromised over an extended period.⁴⁷⁷ It is striking that the World Health Organization (WHO) estimates that of the 10.6 million children younger than 5 years of age who died from 2000 to 2003, the underlying cause of death in 53% of cases was undernutrition, and in 18% of these children deaths were attributed to diarrhea.⁸⁹

Molecular Epidemiologic Studies

Initial investigations of the molecular epidemiology of human rotaviruses utilized gel electrophoresis and evaluated the individual genomic migration patterns of the segmented genomic dsRNA for strain identification (electropherotype), comparison, and epidemiologic correlations.³⁴⁰ For example, analysis of rotaviruses isolated from 116 children hospitalized with gastroenteritis in Melbourne, Australia, between 1973 and 1979 identified 17 different electropherotypes.⁶³³ In this study, a single electropherotype was predominant at any given time but was accompanied by less common types, and these predominant electropherotypes tended to change over time during a season and between seasons. The major exception to this pattern was the finding that the electropherotypes present in newborn nurseries tended to remain constant for years.¹³⁴ In addition to providing evidence for genetic diversity of human rotaviruses and heterogeneity of circulating rotaviruses, analysis of electropherotypes has also provided a simple and sensitive method for tracing the spread of rotavirus through a population group. The electropherotype cannot be used, however, to predict virulence or for serotypic classification.^{19,269}

Another early molecular approach to epidemiologic studies was RNA/RNA hybridization; this technique employs labeled ssRNA viral transcripts as probes for genomic dsRNA. These studies identified two major families (genogroups) of human rotaviruses and showed that human strains had a general lack of homology with animal strains. Occasional human/human and human/animal genogroup reassortants and some rare human genogroups have been observed using hybridization.^{250,529,531}

It was proposed that the term *genogroup* be adopted in lieu of *family* to conform to taxonomic hierarchy.⁵³⁰ Recent advances in the speed of full genomic sequencing as well as its reduction in cost make it likely that electropherotyping and RNA/RNA hybridization approaches will be replaced with genome sequencing in future epidemiologic studies.

IMMUNITY

The mechanisms responsible for generating protective immunity to rotavirus infections and illness following vaccination or natural infection are not completely understood, especially in humans where detailed examination of the acquired cellular immune response (B cells, T cells) in young children has been limited because of the difficulty in obtaining timely and sufficient specimens. The contribution of innate immunity to the control of rotavirus infection has only recently been examined, and these studies have been primarily in animal models. In general, a correlation has been found between the level of serum antibody in animals and people and protection from illness, but this correlation has not been absolute and it seems likely that serum antibody levels generally reflect other, less easily measured immune effector functions such as mucosal antibody titers or levels of virus-specific memory B cells in the gut.^{15,252,373} The one circumstance where serum antibody levels are likely to be directly related to protection is in newborn children where transplacentally acquired humoral immunity appears to offer some protection from illness early in life.⁶²¹

Because of the complexities inherent in studying the effector mechanisms responsible for the induction and persistence of protective immunity in young children, animal models have been particularly helpful. Animal models have been used to identify the respective roles of the humoral and cellular immune responses, in dissecting the relative importance of systemic and local immunity, in identifying the viral targets of protective immunity to rotavirus infection and/or disease, and in identifying the role of innate immunity.^{185,252,254,681,771,772} There are, however, several important considerations to keep in mind when evaluating experiments on rotavirus immunity in animal models. Many common laboratory and domestic animals undergo natural homologous rotavirus infection with strains that specifically infect that species and generally cause diarrheal disease in the young. In addition, many animal species can be experimentally infected with heterologous rotavirus strains (strains initially isolated from another animal species), and in many cases heterologous rotavirus infection, at high inoculation titer, can also cause diarrheal disease in the heterologous host. In general, heterologous strains do not spread efficiently in a heterologous host, do not cause disease at low inoculation titer, replicate less well than homologous strains in the gastrointestinal tract, and are usually attenuated compared to homologous rotavirus strains in the homologous host. Studies of the determinants of protective immunity in animal models have used both homologous and heterologous strains as challenges to examine the basis for inducing and measuring protective immunity. Unfortunately, it is not entirely clear whether information derived from such studies varies qualitatively or quantitatively or how much the response depends on whether the challenge was homologous or heterologous. Certainly in nature, virtually all disease in humans is caused by homologous

viral infection, at least in developed countries. In addition, most animal models of immunization and subsequent protection are short term (lasting weeks or a month or 2 months at the most) because of the difficulty of maintaining animals in a nonimmune and susceptible state over long periods of time (years), as is the case with rotavirus disease in humans where some children remain unexposed to rotavirus for at least 2 years. In addition, once a small animal (mouse or rabbit) is infected, it is highly or completely resistant to subsequent symptomatic disease and, in some cases, reinfection. Humans, on the other hand, remain susceptible to primary infection and disease over a long period of time (at least 3 years) and are susceptible to multiple reinfections and multiple bouts of rotavirus-associated disease in childhood and, to a lesser degree, in later life. Hence, one must approach animal model data on rotavirus immunity with some caution and realize that it may not be directly applicable to the human condition.

A variety of animal models (mice, rats, rabbits, pigs, calves, lambs, primates, and others) have been used to study rotavirus infection. The mouse and pig models have been the most extensively used, especially from the standpoint of evaluation of immunity, and they are the focus of this review.^{232,254,640,817}

The ability of serum antibody to rotavirus to provide protection from challenge has also been evaluated in animal studies.^{15,185,252,254,373,787}

In various studies, serum antibody was derived transplacentally, via systemic absorption of colostrum, via passive parenteral inoculation with immune serum or purified polyclonal or monoclonal immunoglobulins, or via systemic immunization with inactivated virus, virus-like-particles, or recombinant viral proteins with or without an adjuvant. For example, in an early study, it was observed that newborn calves frequently developed rotavirus diarrhea despite a moderately high level of circulating rotavirus antibodies derived from colostrum⁷⁹⁵; neither the challenge dose nor the relative titer of neutralizing activity in the absorbed colostrum antibodies were well quantified in this study. Passively acquired high levels of serum antibody have been associated with protection in a variety of animal studies, however,^{50,363,373} and if the level of systemic serum antibody is not sufficiently high, protection is limited.⁵⁵³

When examined *in toto*, these systemic antibody studies imply that if the level of circulating antibody is sufficiently high, enough will find its way into the gut lumen and mediate protection. The data are most compatible with the interpretation that it is the ability of systemic antibody to get into the gut lumen that is the critical effector mechanism of protection and not its isotype or its presence in the serum. These studies have generally not taken into account the fact that the efficiency of transfer of serum antibody into the gut (either active or passive) varies from species to species and also with the age of the animal at the time of antibody transfer. Recent studies have clearly demonstrated that in several animal species, including humans, there is an active transport mechanism to move systemic immunoglobulin G (IgG) into the intestinal lumen.³⁰ Of note, the relative sparing of rotavirus infection in the first 2 months of life in children and the correlation of protection with maternal antibody titers at birth provide indirect support for the notion that serum antibody can, under some circumstances, directly mediate local effects in humans as well as animals.⁶²¹

A number of studies in mice have delineated the immune effectors that mediate protection from reinfection and clearance of primary infection. These studies have been facilitated

by the availability of a large number of immunologic reagents to characterize the mouse immune response, by the availability of many useful knockout mouse models, and by the fact that mice have their own homologous rotavirus that causes natural diarrheal disease in suckling mice. Mice are also susceptible, in varying degrees, to a number of heterologous rotaviruses. B cells, and hence antibodies, are critical for the maintenance of long-term, high-level protection from reinfection in mice, and CD8+ T cells mediate short-term reduced susceptibility to reinfection.^{255,256} A protective B-cell response can occur in the absence of T-cell help, although it is substantially reduced compared to the response seen in wild-type mice,²⁵³ and T cells can mediate their antirotavirus effects in the absence of perforin, Fas, and interferon- γ .²⁵⁶ Both B and T cells can clear primary infection, but T cells appear to do this more quickly and, in some studies, more efficiently than B cells. CD8+ T cells can mediate almost complete protection (up to 2 weeks after primary infection) or partial protection (up to 3 months or less after primary infection) from reinfection; however, this protection diminishes greatly 8 months after primary infection.^{187,231,494,496} An important role for CD8+ T cells in the control of primary rotavirus infection was also demonstrated in a homologous gnotobiotic calf model.⁵⁵⁵

Studies using wild-type and various knockout mice have highlighted the importance of intestinal tract homing of both B and T cells, mediated by the $\alpha_4\beta_7$ integrin and CCR9 and CCR10, in promoting rotavirus immunity in the mouse model.^{233,426,427,641,813} Additional studies using IgA-deficient mice showed that in the absence of IgA, compensatory IgG protective immunity is generated,⁵⁴⁵ and that the IgG immunity is also dependent on the ability of B cells to traffic to the gut.⁴²⁷ Consistent with the animal findings, people with selective IgA deficiency resolve rotavirus infection normally and appear to develop compensatory increases in antirotavirus IgG during infection.³⁶⁴ Dietary factors have also been investigated for their influence on the immune response. For example, vitamin A deficiency impairs both serum antibody and cell-mediated immune responses to rotavirus in infant mice.⁹

Several experimental approaches have been used to identify the viral targets of protective humoral immunity. The most definitive of these have been carried out *in vitro* or in animal models. *In vitro* neutralization studies using monospecific hyperimmune or monoclonal antibodies generally have found that VP4 and VP7 are the only two targets of neutralizing antibody, although some data indicate that some antibodies to VP6 can also mediate *in vitro* and *in vivo* neutralization.^{15,91,185,263,305,776}

As discussed elsewhere in this chapter, both VP4 and VP7 come in a variety of antigenic specificities (called P and G serotypes, respectively) that are capable of segregating independently by gene reassortment. Many monoclonal and polyclonal antibodies directed at these two surface proteins preferentially react in a serotype-specific manner. On the other hand, both VP4 and VP7 contain heterotypic epitopes, and antibodies to either protein can have heterotypic specificity as well.⁴⁸¹

The rules governing the induction of homotypic versus heterotypic immunity following natural infection or vaccination are poorly understood for rotavirus as they are for most viral infections. This issue has been difficult to evaluate carefully in animal models because of the relatively short window of susceptibility to infection in the experimental setting, and both homotypic and heterotypic protection have been

shown in animal models.^{81,551,798,817} Recent studies in humans make clear that exposure to infection with a very limited number of VP4 and VP7 serotypes (either from natural infection or vaccination) provides substantial protective immunity to most heterotypic strains. What is still not clear is the basis for this heterotypic immunity.

Two other proteins have been implicated as targets of protective immunity following infection. Although rare, selected antibodies to VP6 appear to be capable of mediating classic viral neutralization.²⁶³ In addition, in a mouse model, selected IgA anti-VP6 monoclonal antibodies were protective despite the fact that they did not have traditional *in vitro* neutralization activity. These antibodies appeared to function intracellularly during transcytosis through gut epithelial cells.^{91,150,235,669} In other studies in the mouse model, CD4+ T cells directed at VP6 were able to mediate protection, and in mice and rabbits, but not pigs, systemic immunization with double-layered (VP2 and VP6) particles or VLPs induced varying levels of resistance to challenge.⁷⁷⁸ Whether VP6 immunity plays any role in the heterotypic nature of immunity seen in people is currently unknown. Finally, the NSP4 virally encoded enterotoxin is a potential target of protective immunity, and studies in mice have demonstrated protection from disease following administration of antibody to this protein. Again, the relevance of this data to people is not known.³⁴⁶

A variety of epidemiologic and serologic studies have provided compelling demonstrations of the development of acquired immunity to rotavirus infection and disease in people over time as well as the recurrent nature of rotavirus infection over a lifetime (Fig. 45.15B). These studies demonstrated that asymptomatic neonatal infection was associated with a subsequent reduction in severe rotavirus disease, but not with lack of reinfection. A large 2-year prospective study in Mexico showed that one or two natural rotavirus infections were highly effective at preventing further severe infections.^{57,747} This protection was both homo- and heterotypic in nature, although

the homotypic response appeared stronger following the first rotavirus exposure than after subsequent infections. These epidemiologic studies did not, however, identify the immunologic determinants of protective immunity.

Some experimental information regarding correlates of rotavirus immunity in people was obtained in an adult volunteer study in which a human rotavirus VP7 (G) serotype 1 (D strain) was orally administered to 18 individuals.^{401,402} Of the 18 volunteers, 5 shed rotavirus and 4 of those 5 developed diarrheal illness. The pre-existing level of serum neutralizing antibodies to the homotypic challenge virus or to a heterotypic VP7 (G) serotype 2 human rotavirus correlated with resistance to illness. The correlation of levels of neutralizing activity in intestinal fluid to resistance was not significant, however. Each of the five ill volunteers developed a serum neutralizing antibody response to the challenge strain and to the heterotypic human rotavirus DS-1 strain (serotype G2) as well as to a totally heterotypic bovine rotavirus NCDV strain (serotype G6). The prechallenge sera from this study were later re-examined by a competitive epitope-blocking immunoassay for antibody levels against several well-defined VP7 and VP4 neutralization epitopes.^{300,680} These studies correlated both homo- and heterotypic blocking activity to VP7 with resistance to disease. Confirmation of the importance of antibodies to protection in people was provided during a later series of challenge and rechallenge studies in which serum rotavirus IgG or jejunal neutralizing antibodies were observed to correlate with protection against infection and illness.^{401,402} In a third series of studies, however, serum and jejunal rotavirus antibodies did not correlate with resistance.^{774,775,777}

In other studies, salivary IgA antibodies, as measured by ELISA, were proposed as a surrogate for the level of intestinal rotavirus antibodies.⁷⁷⁹ Rotavirus serum IgA levels were also shown to be correlated with resistance to severe rotavirus illness.³³⁸ During a study of infants 1 to 24 months of age and young children residing in an orphanage, a significant

FIGURE 45.15. Relative quantities of rotavirus (RV)-specific antibodies and T cells during the natural history of RV infections. In people, rotavirus infections generally occur multiple times over a life span with decreasing frequency as exposures increase. Late in life when exposures are often reduced, increased susceptibility can occur. Protection from severe disease can be mediated by passively acquired immunoglobulin G (IgG) antibody at birth or from actively acquired IgA or IgG antibody following subsequent infection or vaccination. Protection from subsequent infections or mild disease (indicated by diminished viral shedding and immune boosting) is relative and likely depends on a number of factors but primarily the level of local and systemic antibodies. CD8+ T cells play a role in the timely resolution of rotavirus infection in animal models, but their role in humans is less well documented. Other critical immune factors like intestinal B and T cells have not been fully studied. (Lines represent a typical set of responses but inter-individual variations are frequent.)

correlation was observed between homotypic serum neutralizing antibodies and resistance to disease.¹²⁴ The association between fecal (IgA) and serum (IgG) antirotavirus antibody titers and protection against infection and illness was also investigated in 100 children younger than 18 months of age attending daycare centers in the United States for one or two rotavirus seasons.^{480,549} During the two seasons, seven outbreaks of G1 serotype and one of G3 serotype were detected. These studies concluded that (a) a rotavirus-specific fecal IgA titer of at least 1:80 correlated with protection against infection and a titer of at least 1:20 correlated with protection against illness; (b) a pre-existing serum antirotavirus IgA titer of greater than 1:200 or an IgG titer of greater than 1:800 was associated with protection against infection; and (c) a high level of pre-existing G type-specific blocking antibody was associated with protection against infection. Similar results were obtained from a study conducted in Australia: a direct correlation was observed between high levels of antirotavirus intestinal IgA antibody and protection against natural rotavirus infection and illness.¹⁵¹ In a heterologous gnotobiotic piglet model, a direct association was observed between the degree of protection and the level of intestinal IgA antibody-secreting cell response as well as serum IgA, intestinal IgA, and intestinal IgG titers.^{727,816} In mice, antirotavirus intestinal or serum IgA correlates with protection against homologous or heterologous rotavirus infection.^{231,495}
